

## **1. What is meant by Digital Image Processing? Explain how digital images can be represented?**

An image may be defined as a two-dimensional function,  $f(x, y)$ , where  $x$  and  $y$  are spatial (plane) coordinates, and the amplitude of  $f$  at any pair of coordinates  $(x, y)$  is called the intensity or gray level of the image at that point.

When  $x$ ,  $y$ , and the amplitude values of  $f$  are all finite, discrete quantities, we call the image a digital image. The field of digital image processing refers to processing digital images by means of a digital computer.

Digital image is composed of a finite number of elements, each of which has a particular location and value. These elements are referred to as picture elements, image elements, pels, and pixels. Pixel is the term most widely used to denote the elements of a digital image.

Vision is the most advanced of our senses, so it is not surprising that images play the single most important role in human perception. However, unlike humans, who are limited to the visual band of the electromagnetic (EM) spectrum, imaging machines cover almost the entire EM spectrum, ranging from gamma to radio waves. They can operate on images generated by sources that humans are not accustomed to associating with images. These include ultra-sound, electron microscopy, and computer-generated images. Thus, digital image processing encompasses a wide and varied field of applications. There is no general agreement among authors regarding where image processing stops and other related areas, such as image analysis and computer vision, start. Sometimes a distinction is made by defining image processing as a discipline in which both the input and output of a process are images. We believe this to be a limiting and somewhat artificial boundary. For example, under this definition, even the trivial task of computing the average intensity of an image (which yields a single number) would not be considered an image processing operation. On the other hand, there are fields such as computer vision whose ultimate goal is to use computers to emulate human vision, including learning and being able to make inferences and take actions based on visual inputs. This area itself is a branch of artificial intelligence (AI) whose objective is to emulate human intelligence. The field of AI is in its earliest stages of infancy in terms of development, with progress having been much slower than originally anticipated. The area of image analysis (also called image understanding) is in between image processing and computer vision.

There are no clear-cut boundaries in the continuum from image processing at one end to computer vision at the other. However, one useful paradigm is to consider three types of computerized processes in this continuum: low-, mid-, and high-level processes. Low-level processes involve primitive operations such as image preprocessing to reduce noise, contrast enhancement, and image sharpening. A low-level process is characterized by the fact that both its inputs and outputs are images.

Mid-level processing on images involves tasks such as segmentation (partitioning an image into regions or objects), description of those objects to reduce them to a form suitable for computer processing, and classification (recognition) of individual objects. A mid-level process is characterized by the fact that its inputs generally are images, but its outputs are attributes extracted from those images (e.g., edges, contours, and the identity of individual objects). Finally, higher-level processing involves “making sense” of an ensemble of recognized objects, as in image analysis, and, at the far end of the continuum, performing the cognitive functions normally associated with vision and, in addition, encompasses processes that extract attributes from images, up to and including the recognition of individual objects. As a simple illustration to clarify these concepts, consider the area of automated analysis of text. The processes of acquiring an image of the area containing the text, preprocessing that image, extracting (segmenting) the individual characters, describing the characters in a form suitable for computer processing, and recognizing those individual characters are in the scope of what we call digital image processing.

### Representing Digital Images:

We will use two principal ways to represent digital images. Assume that an image  $f(x, y)$  is sampled so that the resulting digital image has  $M$  rows and  $N$  columns. The values of the coordinates  $(x, y)$  now become discrete quantities. For notational clarity and convenience, we shall use integer values for these discrete coordinates. Thus, the values of the coordinates at the origin are  $(x, y) = (0, 0)$ . The next coordinate values along the first row of the image are represented as  $(x, y) = (0, 1)$ . It is important to keep in mind that the notation  $(0, 1)$  is used to signify the second sample along the first row. It does not mean that these are the actual values of physical coordinates when the image was sampled. Figure 1 shows the coordinate convention used.

**Fig 1 Coordinate convention used to represent digital images**

The notation introduced in the preceding paragraph allows us to write the complete  $M \times N$  digital image in the following compact matrix form:

$$f(x, y) = \begin{bmatrix} f(0, 0) & f(0, 1) & \cdots & f(0, N - 1) \\ f(1, 0) & f(1, 1) & \cdots & f(1, N - 1) \\ \vdots & \vdots & & \vdots \\ f(M - 1, 0) & f(M - 1, 1) & \cdots & f(M - 1, N - 1) \end{bmatrix}.$$

The right side of this equation is by definition a digital image. Each element of this matrix array is called an image element, picture element, pixel, or pel.

## 2. What are the fundamental steps in Digital Image Processing?

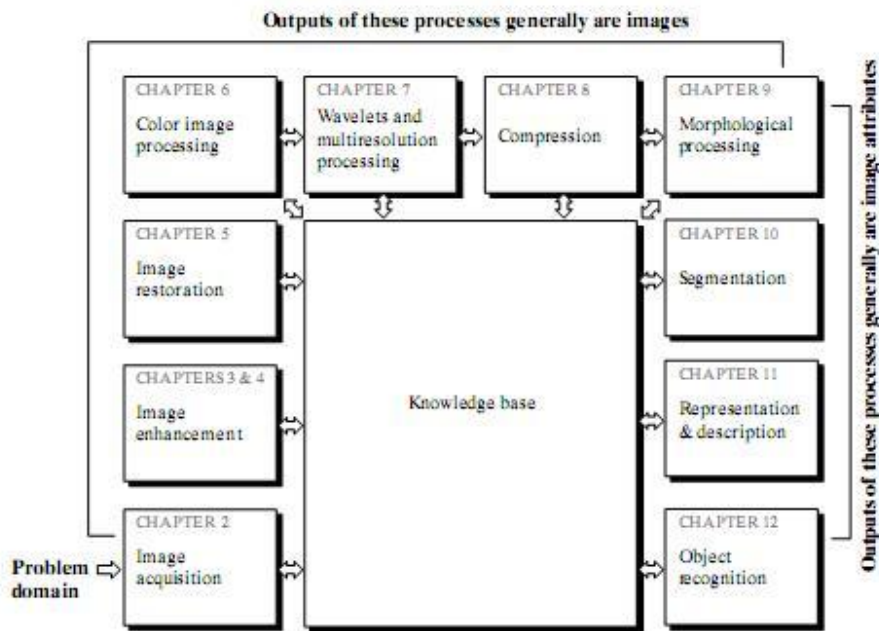

### Fundamental Steps in Digital Image Processing:

Image acquisition is the first process shown in Fig.2. Note that acquisition could be as simple as being given an image that is already in digital form. Generally, the image acquisition stage involves preprocessing, such as scaling.

Image enhancement is among the simplest and most appealing areas of digital image processing. Basically, the idea behind enhancement techniques is to bring out detail that is obscured, or simply to highlight certain features of interest in an image. A familiar example of enhancement is when we increase the contrast of an image because “it looks better.” It is important to keep in mind that enhancement is a very subjective area of image processing.

Image restoration is an area that also deals with improving the appearance of an image. However, unlike enhancement, which is subjective, image restoration is objective, in the sense that restoration techniques tend to be based on mathematical or probabilistic models of image degradation. Enhancement, on the other hand, is based on human subjective preferences regarding what constitutes a “good” enhancement result.

Color image processing is an area that has been gaining in importance because of the significant increase in the use of digital images over the Internet.

**Fig.2. Fundamental steps in Digital Image Processing**

Wavelets are the foundation for representing images in various degrees of resolution. Compression, as the name implies, deals with techniques for reducing the storage required to save an image, or the bandwidth required to transmit it. Although storage technology has improved significantly over the past decade, the same cannot be said for transmission capacity. This is true particularly in uses of the Internet, which are characterized by significant pictorial content. Image compression is familiar (perhaps inadvertently) to most users of computers in the form of image file extensions, such as the jpg file extension used in the JPEG (Joint Photographic Experts Group) image compression standard.

Morphological processing deals with tools for extracting image components that are useful in the representation and description of shape.

Segmentation procedures partition an image into its constituent parts or objects. In general, autonomous segmentation is one of the most difficult tasks in digital image processing. A rugged segmentation procedure brings the process a long way toward successful solution of imaging problems that require objects to be identified individually. On the other hand, weak or erratic

segmentation algorithms almost always guarantee eventual failure. In general, the more accurate the segmentation, the more likely recognition is to succeed.

Representation and description almost always follow the output of a segmentation stage, which usually is raw pixel data, constituting either the boundary of a region (i.e., the set of pixels separating one image region from another) or all the points in the region itself. In either case, converting the data to a form suitable for computer processing is necessary. The first decision that must be made is whether the data should be represented as a boundary or as a complete region. Boundary representation is appropriate when the focus is on external shape characteristics, such as corners and inflections. Regional representation is appropriate when the focus is on internal properties, such as texture or skeletal shape. In some applications, these representations complement each other. Choosing a representation is only part of the solution for transforming raw data into a form suitable for subsequent computer processing. A method must also be specified for describing the data so that features of interest are highlighted. Description, also called feature selection, deals with extracting attributes that result in some quantitative information of interest or are basic for differentiating one class of objects from another.

Recognition is the process that assigns a label (e.g., “vehicle”) to an object based on its descriptors. We conclude our coverage of digital image processing with the development of methods for recognition of individual objects.

### **3. What are the components of an Image Processing System?**

#### **Components of an Image Processing System:**

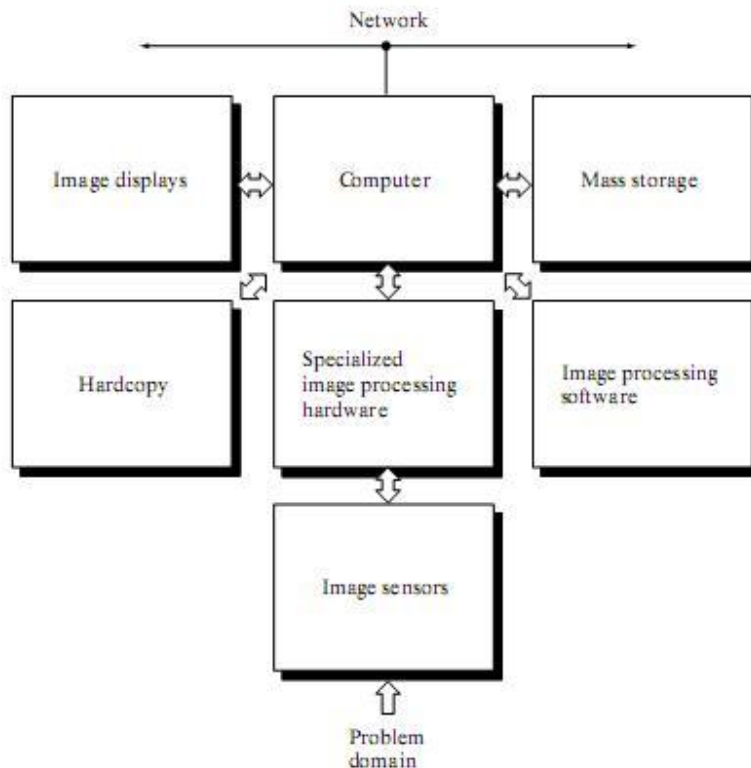

As recently as the mid-1980s, numerous models of image processing systems being sold throughout the world were rather substantial peripheral devices that attached to equally substantial host computers. Late in the 1980s and early in the 1990s, the market shifted to image processing hardware in the form of single boards designed to be compatible with industry standard buses and to fit into engineering workstation cabinets and personal computers. In addition to lowering costs, this market shift also served as a catalyst for a significant number of new companies whose specialty is the development of software written specifically for image processing.

Although large-scale image processing systems still are being sold for massive imaging applications, such as processing of satellite images, the trend continues toward miniaturizing and blending of general-purpose small computers with specialized image processing hardware. Figure 3 shows the basic components comprising a typical general-purpose system used for digital image processing. The function of each component is discussed in the following

paragraphs, starting with image sensing.

With reference to sensing, two elements are required to acquire digital images. The first is a physical device that is sensitive to the energy radiated by the object we wish to image. The second, called a digitizer, is a device for converting the output of the physical sensing device into digital form. For instance, in a digital video camera, the sensors produce an electrical output proportional to light intensity. The digitizer converts these outputs to digital data.

Specialized image processing hardware usually consists of the digitizer just mentioned, plus hardware that performs other primitive operations, such as an arithmetic logic unit (ALU), which performs arithmetic and logical operations in parallel on entire images. One example of how an ALU is used is in averaging images as quickly as they are digitized, for the purpose of noise reduction. This type of hardware sometimes is called a front-end subsystem, and its most distinguishing characteristic is speed. In other words, this unit performs functions that require fast data throughputs (e.g., digitizing and averaging video images at 30 frames) that the typical main computer cannot handle.

**Fig.3. Components of a general purpose Image Processing System**

The computer in an image processing system is a general-purpose computer and can range from a PC to a supercomputer. In dedicated applications, sometimes specially designed computers are used to achieve a required level of performance, but our interest here is on general-purpose image processing systems. In these systems, almost any well-equipped PC-type machine is suitable for offline image processing tasks.

Software for image processing consists of specialized modules that perform specific tasks. A well-designed package also includes the capability for the user to write code that, as a minimum, utilizes the specialized modules. More sophisticated software packages allow the integration of those modules and general-purpose software commands from at least one computer language.

Mass storage capability is a must in image processing applications. An image of size  $1024 \times 1024$  pixels, in which the intensity of each pixel is an 8-bit quantity, requires one megabyte of storage space if the image is not compressed. When dealing with thousands, or even millions, of images, providing adequate storage in an image processing system can be a challenge. Digital storage for image processing applications falls into three principal categories: (1) short-term storage for use during processing, (2) on-line storage for relatively fast re-call, and (3) archival storage, characterized by infrequent access. Storage is measured in bytes (eight bits), Kbytes (one thousand bytes), Mbytes (one million bytes), Gbytes (meaning giga, or one billion, bytes), and Tbytes (meaning tera, or one trillion, bytes). One method of providing short-term storage is computer memory. Another is by specialized boards, called frame buffers, that store one or more images and can be accessed rapidly, usually at video rates (e.g., at 30 complete images per second). The latter method allows virtually instantaneous image zoom, as well as scroll (vertical shifts) and pan (horizontal shifts). Frame buffers usually are housed in the specialized image processing hardware unit shown in Fig.3. Online storage generally takes the form of magnetic disks or optical-media storage. The key factor characterizing on-line storage is frequent access to the stored data. Finally, archival storage is characterized by massive storage requirements but infrequent need for access. Magnetic tapes and optical disks housed in “jukeboxes” are the usual media for archival applications.

Image displays in use today are mainly color (preferably flat screen) TV monitors. Monitors are

driven by the outputs of image and graphics display cards that are an integral part of the computer system. Seldom are there requirements for image display applications that cannot be met by display cards available commercially as part of the computer system. In some cases, it is necessary to have stereo displays, and these are implemented in the form of headgear containing two small displays embedded in goggles worn by the user.

Hardcopy devices for recording images include laser printers, film cameras, heat-sensitive devices, inkjet units, and digital units, such as optical and CD-ROM disks. Film provides the highest possible resolution, but paper is the obvious medium of choice for written material. For presentations, images are displayed on film transparencies or in a digital medium if image projection equipment is used. The latter approach is gaining acceptance as the standard for image presentations.

Networking is almost a default function in any computer system in use today. Because of the large amount of data inherent in image processing applications, the key consideration in image transmission is bandwidth. In dedicated networks, this typically is not a problem, but communications with remote sites via the Internet are not always as efficient. Fortunately, this situation is improving quickly as a result of optical fiber and other broadband technologies.

#### **4. Explain about elements of visual perception.**

##### **Elements of Visual Perception:**

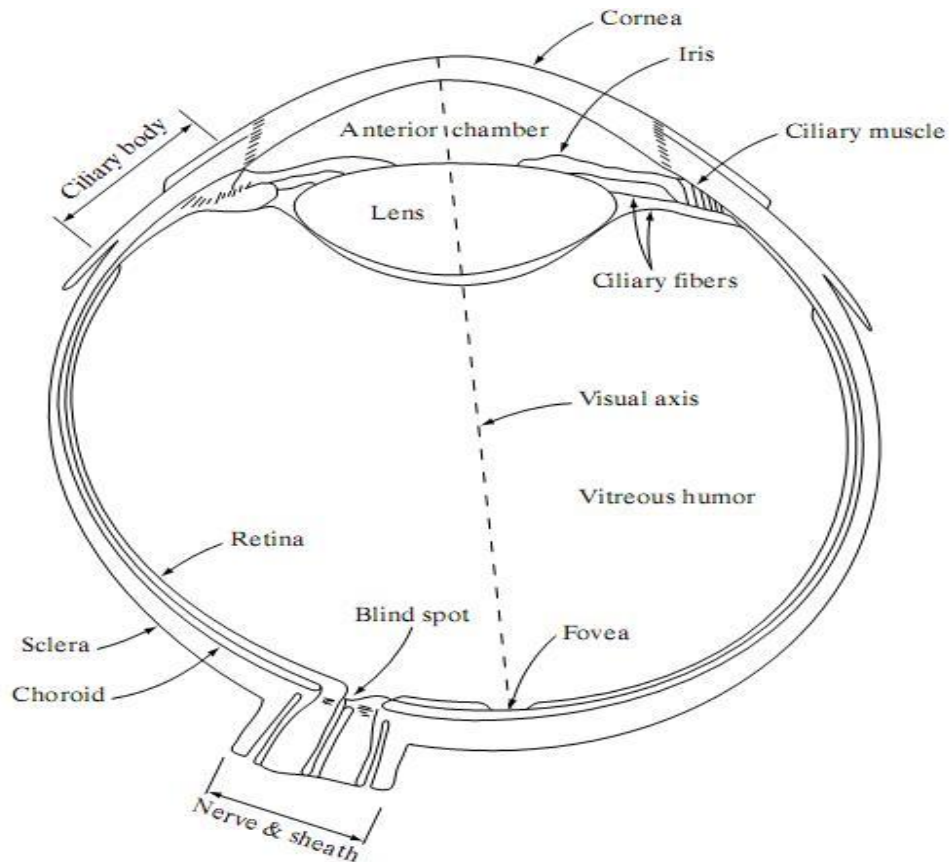

Although the digital image processing field is built on a foundation of mathematical and probabilistic formulations, human intuition and analysis play a central role in the choice of one technique versus another, and this choice often is made based on subjective, visual judgments.

##### **(1) Structure of the Human Eye:**

Figure 4.1 shows a simplified horizontal cross section of the human eye. The eye is nearly a sphere, with an average diameter of approximately 20 mm. Three membranes enclose the eye: the cornea and sclera outer cover; the choroid; and the retina. The cornea is a tough, transparent tissue that covers the anterior surface of the eye. Continuous with the cornea, the sclera is an opaque membrane that encloses the remainder of the optic globe. The choroid lies directly below the sclera. This membrane contains a network of blood vessels that serve as the major source of nutrition to the eye. Even superficial injury to the choroid, often not deemed serious, can lead to severe eye damage as a result of inflammation that restricts blood flow. The choroid coat is

heavily pigmented and hence helps to reduce the amount of extraneous light entering the eye and the backscatter within the optical globe. At its anterior extreme, the choroid is divided into the ciliary body and the iris diaphragm. The latter contracts or expands to control the amount of light that enters the eye. The central opening of the iris (the pupil) varies in diameter from approximately 2 to 8 mm. The front of the iris contains the visible pigment of the eye, whereas the back contains a black pigment.

The lens is made up of concentric layers of fibrous cells and is suspended by fibers that attach to the ciliary body. It contains 60 to 70% water, about 6% fat, and more protein than any other tissue in the eye. The lens is colored by a slightly yellow pigmentation that increases with age. In extreme cases, excessive clouding of the lens, caused by the affliction commonly referred to as cataracts, can lead to poor color discrimination and loss of clear vision. The lens absorbs approximately 8% of the visible light spectrum, with relatively higher absorption at shorter wavelengths. Both infrared and ultraviolet light are absorbed appreciably by proteins within the lens structure and, in excessive amounts, can damage the eye.

**Fig.4.1 Simplified diagram of a cross section of the human eye.**

The innermost membrane of the eye is the retina, which lines the inside of the wall's entire posterior portion. When the eye is properly focused, light from an object outside the eye is imaged on the retina. Pattern vision is afforded by the distribution of discrete light receptors over the surface of the retina. There are two classes of receptors: cones and rods. The cones in each eye number between 6 and 7 million. They are located primarily in the central portion of the retina, called the fovea, and are highly sensitive to color. Humans can resolve fine details with these cones largely because each one is connected to its own nerve end. Muscles controlling the eye rotate the eyeball until the image of an object of interest falls on the fovea. Cone vision is called photopic or bright-light vision. The number of rods is much larger: Some 75 to 150 million are distributed over the retinal surface. The larger area of distribution and the fact that several rods are connected to a single nerve end reduce the amount of detail discernible by these receptors. Rods serve to give a general, overall picture of the field of view. They are not involved in color vision and are sensitive to low levels of illumination. For example, objects that appear brightly colored in daylight when seen by moonlight appear as colorless forms because only the rods are stimulated. This phenomenon is known as scotopic or dim-light vision.

## (2) Image Formation in the Eye:

The principal difference between the lens of the eye and an ordinary optical lens is that the former is flexible. As illustrated in Fig. 4.1, the radius of curvature of the anterior surface of the lens is greater than the radius of its posterior surface. The shape of the lens is controlled by tension in the fibers of the ciliary body. To focus on distant objects, the controlling muscles cause the lens to be relatively flattened. Similarly, these muscles allow the lens to become thicker in order to focus on objects near the eye. The distance between the center of the lens and the retina (called the focal length) varies from approximately 17 mm to about 14 mm, as the refractive power of the lens increases from its minimum to its maximum.

**Fig.4.2. Graphical representation of the eye looking at a palm tree Point C is the optical center of the lens.**

When the eye focuses on an object farther away than about 3 m, the lens exhibits its lowest refractive power. When the eye focuses on a nearby object, the lens is most strongly refractive. This information makes it easy to calculate the size of the retinal image of any object. In Fig. 4.2, for example, the observer is looking at a tree 15 m high at a distance of 100 m. makes it easy to calculate the size of the retinal image of any object. In Fig. 4.2, for example, the observer is looking at a tree 15 m high at a distance of 100 m.

If  $h$  is the height in mm of that object in the retinal image, the geometry of Fig.4.2 yields  $15/100=h/17$  or  $h=2.55\text{mm}$ . The retinal image is reflected primarily in the area of the fovea. Perception then takes place by the relative excitation of light receptors, which transform radiant energy into electrical impulses that are ultimately decoded by the brain.

### (3) Brightness Adaptation and Discrimination:

Because digital images are displayed as a discrete set of intensities, the eye's ability to discriminate between different intensity levels is an important consideration in presenting image-processing results. The range of light intensity levels to which the human visual system can adapt is enormous—on the order of  $10^{10}$ —from the scotopic threshold to the glare limit. Experimental evidence indicates that subjective brightness (intensity as perceived by the human visual system) is a logarithmic function of the light intensity incident on the eye. Figure 4.3, a plot of light intensity versus subjective brightness, illustrates this characteristic. The long solid curve represents the range of intensities to which the visual system can adapt. In photopic vision alone, the range is about  $10^6$ . The transition from scotopic to photopic vision is gradual over the approximate range from 0.001 to 0.1 millilambert ( $-3$  to  $-1$  mL in the log scale), as the double branches of the adaptation curve in this range show.

**Fig.4.3. Range of Subjective brightness sensations showing a particular adaptation level.**

The essential point in interpreting the impressive dynamic range depicted in Fig.4.3 is that the visual system cannot operate over such a range simultaneously. Rather, it accomplishes this large variation by changes in its overall sensitivity, a phenomenon known as brightness adaptation. The total range of distinct intensity levels it can discriminate simultaneously is rather small when compared with the total adaptation range. For any given set of conditions, the current sensitivity level of the visual system is called the brightness adaptation level, which may correspond, for example, to brightness  $B_a$  in Fig. 4.3. The short intersecting curve represents the range of subjective brightness that the eye can perceive when adapted to this level. This range is rather restricted, having a level  $B_b$  at and below which all stimuli are perceived as indistinguishable blacks. The upper (dashed) portion of the curve is not actually restricted but, if extended too far, loses its meaning because much higher intensities would simply raise the adaptation level higher than  $B_a$ .

## 5. Explain the process of image acquisition.

### Image Sensing and Acquisition:

The types of images in which we are interested are generated by the combination of an “illumination” source and the reflection or absorption of energy from that source by the elements of the “scene” being imaged. We enclose illumination and scene in quotes to emphasize the fact that they are considerably more general than the familiar situation in which a visible light source illuminates a common everyday 3-D (three-dimensional) scene. For example, the illumination may originate from a source of electromagnetic energy such as radar, infrared, or X-ray energy. But, as noted earlier, it could originate from less traditional sources, such as ultrasound or even a computer-generated illumination pattern.

Similarly, the scene elements could be familiar objects, but they can just as easily be molecules, buried rock formations, or a human brain. We could even image a source, such as acquiring images of the sun. Depending on the nature of the source, illumination energy is reflected from, or transmitted through, objects. An example in the first category is light reflected from a planar surface. An example in the second category is when X-rays pass through a patient’s body for the purpose of generating a diagnostic X-ray film. In some applications, the reflected or transmitted energy is focused onto a photo converter (e.g., a phosphor screen), which converts the energy into visible light. Electron microscopy and some applications of gamma imaging use this approach.

Figure 5.1 shows the three principal sensor arrangements used to transform illumination energy into digital images. The idea is simple: Incoming energy is transformed into a voltage by the

combination of input electrical power and sensor material that is responsive to the particular type of energy being detected. The output voltage waveform is the response of the sensor(s), and a digital quantity is obtained from each sensor by digitizing its response.

**Fig.5.1 (a) Single imaging Sensor (b) Line sensor (c) Array sensor**

### (1) Image Acquisition Using a Single Sensor:

Figure 5.1 (a) shows the components of a single sensor. Perhaps the most familiar sensor of this type is the photodiode, which is constructed of silicon materials and whose output voltage waveform is proportional to light. The use of a filter in front of a sensor improves selectivity. For example, a green (pass) filter in front of a light sensor favors light in the green band of the color spectrum. As a consequence, the sensor output will be stronger for green light than for other components in the visible spectrum.

In order to generate a 2-D image using a single sensor, there has to be relative displacements in both the x- and y-directions between the sensor and the area to be imaged. Figure 5.2 shows an arrangement used in high-precision scanning, where a film negative is mounted onto a drum whose mechanical rotation provides displacement in one dimension. The single sensor is mounted on a lead screw that provides motion in the perpendicular direction. Since mechanical motion can be controlled with high precision, this method is an inexpensive (but slow) way to obtain high-resolution images. Other similar mechanical arrangements use a flat bed, with the sensor moving in two linear directions. These types of mechanical digitizers sometimes are referred to as microdensitometers.

**Fig.5.2. Combining a single sensor with motion to generate a 2-D image**

### (2) Image Acquisition Using Sensor Strips:

A geometry that is used much more frequently than single sensors consists of an in-line arrangement of sensors in the form of a sensor strip, as Fig. 5.1 (b) shows. The strip provides imaging elements in one direction. Motion perpendicular to the strip provides imaging in the other direction, as shown in Fig. 5.3 (a). This is the type of arrangement used in most flat bed scanners. Sensing devices with 4000 or more in-line sensors are possible. In-line sensors are used routinely in airborne imaging applications, in which the imaging system is mounted on an aircraft that flies at a constant altitude and speed over the geographical area to be imaged. One-dimensional imaging sensor strips that respond to various bands of the electromagnetic spectrum are mounted perpendicular to the direction of flight. The imaging strip gives one line of an image at a time, and the motion of the strip completes the other dimension of a two-dimensional image. Lenses or other focusing schemes are used to project the area to be scanned onto the sensors.

Sensor strips mounted in a ring configuration are used in medical and industrial imaging to obtain cross-sectional (“slice”) images of 3-D objects, as Fig. 5.3 (b) shows. A rotating X-ray source provides illumination and the portion of the sensors opposite the source collect the X-ray energy that pass through the object (the sensors obviously have to be sensitive to X-ray energy). This is the basis for medical and industrial computerized axial tomography (CAT). It is important to note that the output of the sensors must be processed by reconstruction algorithms whose objective is to transform the sensed data into meaningful cross-sectional images.

In other words, images are not obtained directly from the sensors by motion alone; they require extensive processing. A 3-D digital volume consisting of stacked images is generated as the object is moved in a direction perpendicular to the sensor ring. Other modalities of imaging based on the CAT principle include magnetic resonance imaging (MRI) and positron emission tomography (PET). The illumination sources, sensors, and types of images are different, but conceptually they are very similar to the basic imaging approach shown in Fig. 5.3 (b).

**Fig.5.3 (a) Image acquisition using a linear sensor strip (b) Image acquisition using a circular sensor strip.**

### (3) Image Acquisition Using Sensor Arrays:

Figure 5.1 (c) shows individual sensors arranged in the form of a 2-D array. Numerous electromagnetic and some ultrasonic sensing devices frequently are arranged in an array format. This is also the predominant arrangement found in digital cameras. A typical sensor for these cameras is a CCD array, which can be manufactured with a broad range of sensing properties and can be packaged in rugged arrays of  $4000 * 4000$  elements or more. CCD sensors are used widely in digital cameras and other light sensing instruments. The response of each sensor is proportional to the integral of the light energy projected onto the surface of the sensor, a property that is used in astronomical and other applications requiring low noise images. Noise reduction is achieved by letting the sensor integrate the input light signal over minutes or even hours. Since the sensor array shown in Fig. 5.4 (c) is two dimensional, its key advantage is that a complete image can be obtained by focusing the energy pattern onto the surface of the array. The principal manner in which array sensors are used is shown in Fig.5.4. This figure shows the energy from an illumination source being reflected from a scene element, but, as mentioned at the beginning of this section, the energy also could be transmitted through the scene elements. The first function performed by the imaging system shown in Fig.5.4 (c) is to collect the incoming energy and focus it onto an image plane. If the illumination is light, the front end of the imaging system is a lens, which projects the viewed scene onto the lens focal plane, as Fig. 2.15(d) shows. The sensor array, which is coincident with the focal plane, produces outputs proportional to the integral of the light received at each sensor. Digital and analog circuitry sweep these outputs and converts them to a video signal, which is then digitized by another section of the imaging system. The output is a digital image, as shown diagrammatically in Fig. 5.4 (e).

**Fig.5.4 An example of the digital image acquisition process (a) Energy (“illumination”) source (b) An element of a scene (c) Imaging system (d) Projection of the scene onto the image plane (e) Digitized image**

## 6. Explain about image sampling and quantization process.

### Image Sampling and Quantization:

The output of most sensors is a continuous voltage waveform whose amplitude and spatial behavior are related to the physical phenomenon being sensed. To create a digital image, we need to convert the continuous sensed data into digital form. This involves two processes: sampling and quantization.

### Basic Concepts in Sampling and Quantization:

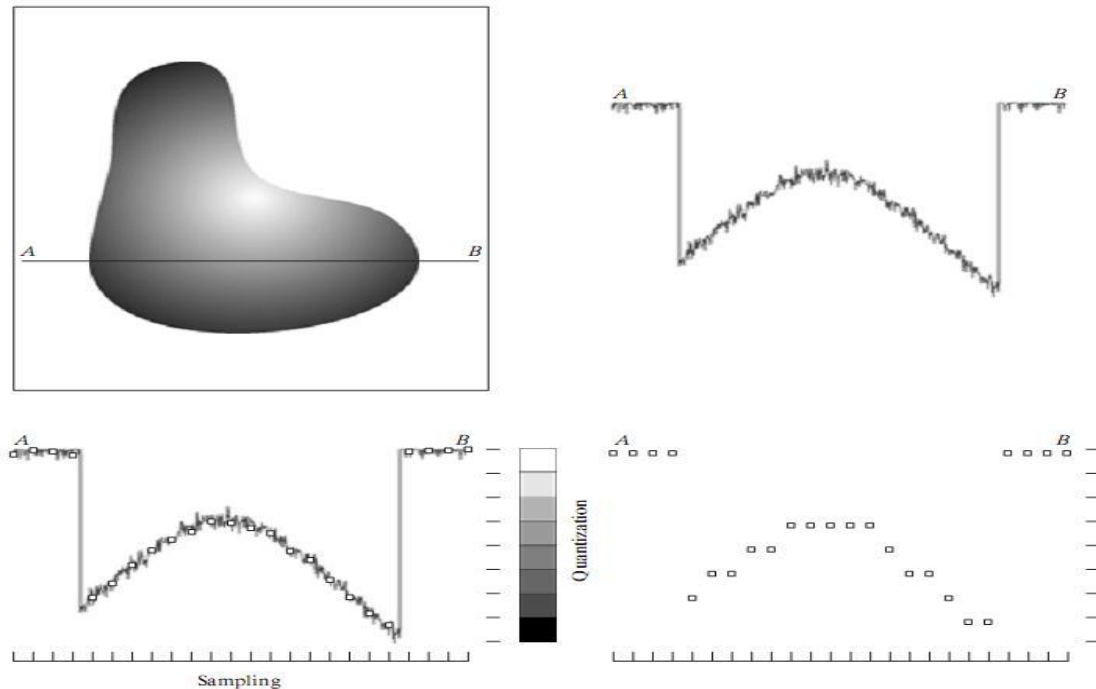

The basic idea behind sampling and quantization is illustrated in Fig.6.1. Figure 6.1(a) shows a continuous image,  $f(x, y)$ , that we want to convert to digital form. An image may be continuous with respect to the x- and y-coordinates, and also in amplitude. To convert it to digital form, we have to sample the function in both coordinates and in amplitude. Digitizing the coordinate values is called sampling. Digitizing the amplitude values is called quantization.

The one-dimensional function shown in Fig.6.1 (b) is a plot of amplitude (gray level) values of the continuous image along the line segment AB in Fig. 6.1(a).The random variations are due to image noise. To sample this function, we take equally spaced samples along line AB, as shown in Fig.6.1 (c).The location of each sample is given by a vertical tick mark in the bottom part of the figure. The samples are shown as small white squares superimposed on the function. The set of these discrete locations gives the sampled function. However, the values of the samples still span (vertically) a continuous range of gray-level values. In order to form a digital function, the gray-level values also must be converted (quantized) into discrete quantities. The right side of Fig. 6.1 (c) shows the gray-level scale divided into eight discrete levels, ranging from black to white. The vertical tick marks indicate the specific value assigned to each of the eight gray levels. The continuous gray levels are quantized simply by assigning one of the eight discrete gray levels to each sample. The assignment is made depending on the vertical proximity of a sample to a vertical tick mark. The digital samples resulting from both sampling and quantization are shown in Fig.6.1 (d). Starting at the top of the image and carrying out this procedure line by line produces a two-dimensional digital image.

Sampling in the manner just described assumes that we have a continuous image in both coordinate directions as well as in amplitude. In practice, the method of sampling is determined by the sensor arrangement used to generate the image. When an image is generated by a single sensing element combined with mechanical motion, as in Fig. 2.13, the output of the sensor is quantized in the manner described above. However, sampling is accomplished by selecting the

number of individual mechanical increments at which we activate the sensor to collect data.

Mechanical motion can be made very exact so, in principle; there is almost no limit as to how fine we can sample an image. However, practical limits are established by imperfections in the optics used to focus on the

**Fig.6.1. Generating a digital image (a) Continuous image (b) A scan line from A to B in the continuous image, used to illustrate the concepts of sampling and quantization (c) Sampling and quantization. (d) Digital scan line**

sensor an illumination spot that is inconsistent with the fine resolution achievable with mechanical displacements. When a sensing strip is used for image acquisition, the number of sensors in the strip establishes the sampling limitations in one image direction. Mechanical motion in the other direction can be controlled more accurately, but it makes little sense to try to achieve sampling density in one direction that exceeds the sampling limits established by the number of sensors in the other. Quantization of the sensor outputs completes the process of generating a digital image.

When a sensing array is used for image acquisition, there is no motion and the number of sensors in the array establishes the limits of sampling in both directions. Figure 6.2 illustrates this concept. Figure 6.2 (a) shows a continuous image projected onto the plane of an array sensor. Figure 6.2 (b) shows the image after sampling and quantization. Clearly, the quality of a digital image is determined to a large degree by the number of samples and discrete gray levels used in sampling

and quantization.

**Fig.6.2. (a) Continuous image projected onto a sensor array (b) Result of image sampling and quantization.**

## **7. Define spatial and gray level resolution. Explain about isopreference curves.**

### **Spatial and Gray-Level Resolution:**

Sampling is the principal factor determining the spatial resolution of an image. Basically, spatial resolution is the smallest discernible detail in an image. Suppose that we construct a chart with vertical lines of width  $W$ , with the space between the lines also having width  $W$ . A line pair consists of one such line and its adjacent space. Thus, the width of a line pair is  $2W$ , and there are  $1/2W$  line pairs per unit distance. A widely used definition of resolution is simply the smallest number of discernible line pairs per unit distance; for example, 100 line pairs per millimeter. Gray-level resolution similarly refers to the smallest discernible change in gray level. We have considerable discretion regarding the number of samples used to generate a digital image, but this

is not true for the number of gray levels. Due to hardware considerations, the number of gray levels is usually an integer power of 2.

The most common number is 8 bits, with 16 bits being used in some applications where enhancement of specific gray-level ranges is necessary. Sometimes we find systems that can digitize the gray levels of an image with 10 or 12 bit of accuracy, but these are the exception rather than the rule. When an actual measure of physical resolution relating pixels and the level of detail they resolve in the original scene are not necessary, it is not uncommon to refer to an L-level digital image of size  $M*N$  as having a spatial resolution of  $M*N$  pixels and a gray-level resolution of L levels.

**Fig.7.1. A 1024\*1024, 8-bit image subsampled down to size 32\*32 pixels The number of allowable gray levels was kept at 256.**

The subsampling was accomplished by deleting the appropriate number of rows and columns from the original image. For example, the 512\*512 image was obtained by deleting every other row and column from the 1024\*1024 image. The 256\*256 image was generated by deleting every

other row and column in the  $512 \times 512$  image, and so on. The number of allowed gray levels was kept at 256. These images show the dimensional proportions between various sampling densities, but their size differences make it difficult to see the effects resulting from a reduction in the number of samples. The simplest way to compare these effects is to bring all the subsampled images up to size  $1024 \times 1024$  by row and column pixel replication. The results are shown in Figs. 7.2 (b) through (f). Figure 7.2 (a) is the same  $1024 \times 1024$ , 256-level image shown in Fig. 7.1; it is repeated to facilitate comparisons.

**Fig. 7.2 (a)  $1024 \times 1024$ , 8-bit image (b)  $512 \times 512$  image resampled into  $1024 \times 1024$  pixels by row and column duplication (c) through (f)  $256 \times 256$ ,  $128 \times 128$ ,  $64 \times 64$ , and  $32 \times 32$  images resampled into  $1024 \times 1024$  pixels**

Compare Fig. 7.2(a) with the  $512 \times 512$  image in Fig. 7.2(b) and note that it is virtually impossible to tell these two images apart. The level of detail lost is simply too fine to be seen on the printed

page at the scale in which these images are shown. Next, the  $256 \times 256$  image in Fig. 7.2(c) shows a very slight fine checkerboard pattern in the borders between flower petals and the black background. A slightly more pronounced graininess throughout the image also is beginning to appear. These effects are much more visible in the  $128 \times 128$  image in Fig. 7.2(d), and they become pronounced in the  $64 \times 64$  and  $32 \times 32$  images in Figs. 7.2 (e) and (f), respectively.

In the next example, we keep the number of samples constant and reduce the number of gray levels from 256 to 2, in integer powers of 2. Figure 7.3(a) is a  $452 \times 374$  CAT projection image, displayed with  $k=8$  (256 gray levels). Images such as this are obtained by fixing the X-ray source in one position, thus producing a 2-D image in any desired direction. Projection images are used as guides to set up the parameters for a CAT scanner, including tilt, number of slices, and range. Figures 7.3(b) through (h) were obtained by reducing the number of bits from  $k=7$  to  $k=1$  while keeping the spatial resolution constant at  $452 \times 374$  pixels. The 256-, 128-, and 64-level images are visually identical for all practical purposes. The 32-level image shown in Fig. 7.3 (d), however, has an almost imperceptible set of very fine ridge like structures in areas of smooth gray levels (particularly in the skull). This effect, caused by the use of an insufficient number of gray levels in smooth areas of a digital image, is called false contouring, so called because the ridges resemble topographic contours in a map. False contouring generally is quite visible in images displayed using 16 or less uniformly spaced gray levels, as the images in Figs. 7.3(e) through (h) show.

**Fig. 7.3 (a) 452\*374, 256-level image (b)–(d) Image displayed in 128, 64, and 32 gray levels, while keeping the spatial resolution constant (e)–(g) Image displayed in 16, 8, 4, and 2 gray levels.**

As a very rough rule of thumb, and assuming powers of 2 for convenience, images of size  $256 \times 256$  pixels and 64 gray levels are about the smallest images that can be expected to be reasonably free of objectionable sampling checker-boards and false contouring.

The results in Examples 7.2 and 7.3 illustrate the effects produced on image quality by varying  $N$  and  $k$  independently. However, these results only partially answer the question of how varying  $N$  and  $k$  affect images because we have not considered yet any relationships that might exist between these two parameters.

An early study by Huang [1965] attempted to quantify experimentally the effects on image quality produced by varying  $N$  and  $k$  simultaneously. The experiment consisted of a set of subjective tests. Images similar to those shown in Fig.7.4 were used. The woman's face is representative of an image with relatively little detail; the picture of the cameraman contains an intermediate amount of detail; and the crowd picture contains, by comparison, a large amount of detail. Sets of these three types of images were generated by varying  $N$  and  $k$ , and observers were then asked to rank them according to their subjective quality. Results were summarized in the form of so-called isopreference curves in the  $Nk$ -plane (Fig.7.5 shows average isopreference curves representative of curves corresponding to the images shown in Fig. 7.4). Each point in the  $Nk$ -plane represents an image having values of  $N$  and  $k$  equal to the coordinates of that point.

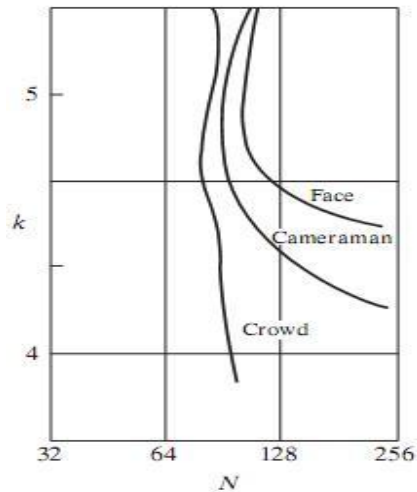

a b c

**Fig.7.4 (a) Image with a low level of detail (b) Image with a medium level of detail (c) Image with a relatively large amount of detail**

Points lying on an isopreference curve correspond to images of equal subjective quality. It was

found in the course of the experiments that the isopreference curves tended to shift right and upward, but their shapes in each of the three image categories were similar to those shown in

Fig. 7.5. This is not unexpected, since a shift up and right in the curves simply means larger values for  $N$  and  $k$ , which implies better picture quality.

**Fig.7.5. Representative isopreference curves for the three types of images in Fig.7.4**

The key point of interest in the context of the present discussion is that isopreference curves tend to become more vertical as the detail in the image increases. This result suggests that for images with a large amount of detail only a few gray levels may be needed. For example, the isopreference curve in Fig.7.5 corresponding to the crowd is nearly vertical. This indicates that, for a fixed value of  $N$ , the perceived quality for this type of image is nearly independent of the number of gray levels used. It is also of interest to note that perceived quality in the other two image categories remained the same in some intervals in which the spatial resolution was increased, but the number of gray levels actually decreased. The most likely reason for this result is that a decrease in  $k$  tends to increase the apparent contrast of an image, a visual effect that humans often perceive as improved quality in an image.

## 8. Explain about Aliasing and Moire patterns.

### Aliasing and Moiré Patterns:

Functions whose area under the curve is finite can be represented in terms of sines and cosines of various frequencies. The sine/cosine component with the highest frequency determines the highest “frequency content” of the function. Suppose that this highest frequency is finite and that the

function is of unlimited duration (these functions are called band-limited functions). Then, the Shannon sampling theorem [Bracewell (1995)] tells us that, if the function is sampled at a rate equal to or greater than twice its highest frequency, it is possible to recover completely the original function from its samples. If the function is undersampled, then a phenomenon called aliasing corrupts the sampled image. The corruption is in the form of additional frequency components being introduced into the sampled function. These are called aliased frequencies. Note that the sampling rate in images is the number of samples taken (in both spatial directions) per unit distance.

As it turns out, except for a special case discussed in the following paragraph, it is impossible to satisfy the sampling theorem in practice. We can only work with sampled data that are finite in duration. We can model the process of converting a function of unlimited duration into a function of finite duration simply by multiplying the unlimited function by a “gating function” that is valued 1 for some interval and 0 elsewhere. Unfortunately, this function itself has frequency components that extend to infinity. Thus, the very act of limiting the duration of a band-limited function causes it to cease being band limited, which causes it to violate the key condition of the sampling theorem. The principal approach for reducing the aliasing effects on an image is to reduce its high-frequency components by blurring the image prior to sampling. However, aliasing is always present in a sampled image. The effect of aliased frequencies can be seen under the right conditions in the form of so called Moiré patterns.

There is one special case of significant importance in which a function of infinite duration can be sampled over a finite interval without violating the sampling theorem. When a function is periodic, it may be sampled at a rate equal to or exceeding twice its highest frequency and it is possible to recover the function from its samples provided that the sampling captures exactly an integer number of periods of the function. This special case allows us to illustrate vividly the Moiré effect. Figure 8 shows two identical periodic patterns of equally spaced vertical bars, rotated in opposite directions and then superimposed on each other by multiplying the two images. A Moiré pattern, caused by a breakup of the periodicity, is seen in Fig.8 as a 2-D sinusoidal (aliased) waveform (which looks like a corrugated tin roof) running in a vertical direction. A similar pattern can appear when images are digitized (e.g., scanned) from a printed page, which consists of periodic ink dots.

s

## 9. Explain about the basic relationships and distance measures between pixels in a digital image.

### Neighbors of a Pixel:

A pixel  $p$  at coordinates  $(x, y)$  has four horizontal and vertical neighbors whose coordinates are given by  $(x+1, y)$ ,  $(x-1, y)$ ,  $(x, y+1)$ ,  $(x, y-1)$ . This set of pixels, called the 4-neighbors of  $p$ , is denoted by  $N_4(p)$ . Each pixel is a unit distance from  $(x, y)$ , and some of the neighbors of  $p$  lie outside the digital image if  $(x, y)$  is on the border of the image.

The four diagonal neighbors of  $p$  have coordinates  $(x+1, y+1)$ ,  $(x+1, y-1)$ ,  $(x-1, y+1)$ ,  $(x-1, y-1)$  and are denoted by  $N_D(p)$ . These points, together with the 4-neighbors, are called the 8-neighbors of  $p$ , denoted by  $N_8(p)$ . As before, some of the points in  $N_D(p)$  and  $N_8(p)$  fall outside the image if  $(x, y)$  is on the border of the image.

### Connectivity:

Connectivity between pixels is a fundamental concept that simplifies the definition of numerous digital image concepts, such as regions and boundaries. To establish if two pixels are connected, it must be determined if they are neighbors and if their gray levels satisfy a specified criterion of similarity (say, if their gray levels are equal). For instance, in a binary image with values 0 and 1, two pixels may be 4-neighbors, but they are said to be connected only if they have the same value.

Let  $V$  be the set of gray-level values used to define adjacency. In a binary image,  $V=\{1\}$  if we are referring to adjacency of pixels with value 1. In a grayscale image, the idea is the same, but set  $V$  typically contains more elements. For example, in the adjacency of pixels with a range of possible gray-level values 0 to 255, set  $V$  could be any subset of these 256 values. We consider three types of adjacency:

- (a) 4-adjacency. Two pixels  $p$  and  $q$  with values from  $V$  are 4-adjacent if  $q$  is in the set  $N_4(p)$ .
- (b) 8-adjacency. Two pixels  $p$  and  $q$  with values from  $V$  are 8-adjacent if  $q$  is in the set  $N_8(p)$ .
- (c) m-adjacency (mixed adjacency). Two pixels  $p$  and  $q$  with values from  $V$  are m-adjacent if
- $q$  is in  $N_4(p)$ , or
  - $q$  is in  $N_D(p)$  and the set has no pixels whose values are from  $V$ .

Mixed adjacency is a modification of 8-adjacency. It is introduced to eliminate the ambiguities that often arise when 8-adjacency is used. For example, consider the pixel arrangement shown in Fig.9 (a) for  $V = \{1\}$ . The three pixels at the top of Fig.9 (b) show multiple (ambiguous) 8-adjacency, as indicated by the dashed lines. This ambiguity is removed by using m-adjacency, as shown in Fig. 9 (c). Two image subsets  $S_1$  and  $S_2$  are adjacent if some pixel in  $S_1$  is adjacent to some pixel in  $S_2$ . It is understood here and in the following definitions that adjacent means 4-, 8-, or m-adjacent. A (digital) path (or curve) from pixel  $p$  with coordinates  $(x, y)$  to pixel  $q$  with coordinates  $(s, t)$  is a sequence of distinct pixels with coordinates

$$(x_0, y_0), (x_1, y_1), \dots, (x_n, y_n)$$

where  $(x_0, y_0) = (x, y)$ ,  $(x_n, y_n) = (s, t)$ , and pixels  $(x_i, y_i)$  and  $(x_{i-1}, y_{i-1})$  are adjacent for  $1 \leq i \leq n$ . In this case,  $n$  is the length of the path. If  $(x_0, y_0) = (x_n, y_n)$ , the path is a closed path. We can define 4-, 8-, or m-paths depending on the type of adjacency specified. For example, the paths shown in Fig. 9 (b) between the northeast and southeast points are 8-paths, and the path in Fig. 9 (c) is an m-path. Note the absence of ambiguity in the m-path. Let  $S$  represent a subset of pixels in an image. Two pixels  $p$  and  $q$  are said to be connected in  $S$  if there exists a path between them consisting entirely of pixels in  $S$ . For any pixel  $p$  in  $S$ , the set of pixels that are connected to it in  $S$  is called a connected component of  $S$ . If it only has one connected component, then set  $S$  is called a connected set.

Let  $R$  be a subset of pixels in an image. We call  $R$  a region of the image if  $R$  is a connected set. The boundary (also called border or contour) of a region  $R$  is the set of pixels in the region that have one or more neighbors that are not in  $R$ . If  $R$  happens to be an entire image (which we recall is a rectangular set of pixels), then its boundary is defined as the set of pixels in the first and last rows and columns of the image. This extra definition is required because an image has no neighbors beyond its border. Normally, when we refer to a region, we are referring to a subset

a b c

**Fig.9 (a) Arrangement of pixels; (b) pixels that are 8-adjacent (shown dashed) to the center pixel; (c) m-adjacency**

of an image, and any pixels in the boundary of the region that happen to coincide with the border of the image are included implicitly as part of the region boundary.

#### Distance Measures:

For pixels  $p$ ,  $q$ , and  $z$ , with coordinates  $(x, y)$ ,  $(s, t)$ , and  $(v, w)$ , respectively,  $D$  is a distance function or metric if

- (a)  $D(p, q) \geq 0$  ( $D(p, q) = 0$  iff  $p = q$ ),
- (b)  $D(p, q) = D(q, p)$ , and
- (c)  $D(p, z) \leq D(p, q) + D(q, z)$ .

The **Euclidean distance** between  $p$  and  $q$  is defined as

$$D_e(p, q) = [(x - s)^2 + (y - t)^2]^{\frac{1}{2}}.$$

For this distance measure, the pixels having a distance less than or equal to some value  $r$  from  $(x, y)$  are the points contained in a disk of radius  $r$  centered at  $(x, y)$ .

The  **$D_4$  distance (also called city-block distance)** between  $p$  and  $q$  is defined as

$$D_4(p, q) = |x - s| + |y - t|.$$

In this case, the pixels having a  $D_4$  distance from  $(x, y)$  less than or equal to some value  $r$  form a diamond centered at  $(x, y)$ . For example, the pixels with  $D_4$  distance  $\leq 2$  from  $(x, y)$  (the center point) form the following contours of constant distance:

$$\begin{array}{ccccc} & & 2 & & \\ & 2 & 1 & 2 & \\ 2 & 1 & 0 & 1 & 2 \\ & 2 & 1 & 2 & \\ & & 2 & & \end{array}$$

The pixels with  $D_4 = 1$  are the 4-neighbors of  $(x, y)$ .

The  **$D_8$  distance (also called chessboard distance)** between  $p$  and  $q$  is defined as

$$D_8(p, q) = \max(|x - s|, |y - t|).$$

In this case, the pixels with  $D_8$  distance from  $(x, y)$  less than or equal to some value  $r$  form a square centered at  $(x, y)$ . For example, the pixels with  $D_8$  distance  $\leq 2$  from  $(x, y)$  (the center point) form the following contours of constant distance:

$$\begin{array}{ccccc} 2 & 2 & 2 & 2 & 2 \\ 2 & 1 & 1 & 1 & 2 \\ 2 & 1 & 0 & 1 & 2 \\ 2 & 1 & 1 & 1 & 2 \\ 2 & 2 & 2 & 2 & 2 \end{array}$$

The pixels with  $D_8=1$  are the 8-neighbors of  $(x, y)$ . Note that the  $D_4$  and  $D_8$  distances between  $p$  and  $q$  are independent of any paths that might exist between the points because these distances involve only the coordinates of the points. If we elect to consider  $m$ -adjacency, however, the  $D_m$  distance between two points is defined as the shortest  $m$ -path between the points. In this case, the

distance between two pixels will depend on the values of the pixels along the path, as well as the values of their neighbors. For instance, consider the following arrangement of pixels and assume that  $p$ ,  $p_2$ , and  $p_4$  have value 1 and that  $p_1$  and  $p_3$  can have a value of 0 or 1:

$$\begin{array}{cc} & p_3 & p_4 \\ p_1 & & p_2 \\ p & & \end{array}$$

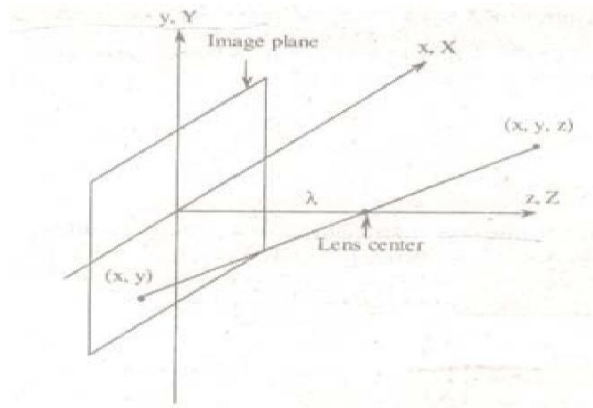

Suppose that we consider adjacency of pixels valued 1 (i.e. = {1}). If  $p_1$  and  $p_3$  are 0, the length of the shortest m-path (the  $D_m$  distance) between  $p$  and  $p_4$  is 2. If  $p_1$  is 1, then  $p_2$  and  $p$  will no longer be m-adjacent (see the definition of m-adjacency) and the length of the shortest m-path becomes 3 (the path goes through the points  $pp_1p_2p_4$ ). Similar comments apply if  $p_3$  is 1 (and  $p_1$  is 0); in this case, the length of the shortest m-path also is 3. Finally, if both  $p_1$  and  $p_3$  are 1 the length of the shortest m-path between  $p$  and  $p_4$  is 4. In this case, the path goes through the sequence of points  $pp_1p_2p_3p_4$ .

## 10. Write about perspective image transformation.

A perspective transformation (also called an imaging transformation) projects 3D points onto a plane. Perspective transformations play a central role in image processing because they provide an approximation to the manner in which an image is formed by viewing a 3D world. These transformations are fundamentally different, because they are nonlinear in that they involve division by coordinate values.

Figure 10 shows a model of the image formation process. The camera coordinate system ( $x, y, z$ ) has the image plane coincident with the  $xy$  plane and the optical axis (established by the center of the lens) along the  $z$  axis. Thus the center of the image plane is at the origin, and the centre of the lens is at coordinates  $(0,0, \lambda)$ . If the camera is in focus for distant objects,  $\lambda$  is the focal length of the lens. Here the assumption is that the camera coordinate system is aligned with the world coordinate system ( $X, Y, Z$ ).

Let  $(X, Y, Z)$  be the world coordinates of any point in a 3-D scene, as shown in the Fig. 10. We assume throughout the following discussion that  $Z > \lambda$ ; that is all points of interest lie in front of the lens. The first step is to obtain a relationship that gives the coordinates  $(x, y)$  of the projection of the point  $(X, Y, Z)$  onto the image plane. This is easily accomplished by the use of similar triangles. With reference to Fig. 10,

**Fig.10 Basic model of the imaging process The camera coordinate system  $(x, y, z)$  is aligned with the world coordinate system  $(X, Y, Z)$**

$$\frac{x}{\lambda} = -\frac{X}{Z - \lambda}$$

$$= \frac{X}{\lambda - Z}$$

$$\frac{y}{\lambda} = -\frac{Y}{Z - \lambda}$$

$$= \frac{Y}{\lambda - Z}$$

Where the negative signs in front of  $X$  and  $Y$  indicate that image points are actually inverted, as the geometry of Fig.10 shows.

The image-plane coordinates of the projected 3-D point follow directly from above equations

$$x = \frac{\lambda X}{\lambda - Z}$$

$$y = \frac{\lambda Y}{\lambda - Z}$$

These equations are nonlinear because they involve division by the variable  $Z$ . Although we could use them directly as shown, it is often convenient to express them in linear matrix form, for rotation, translation and scaling. This is easily accomplished by using homogeneous coordinates.

The homogeneous coordinates of a point with Cartesian coordinates  $(X, Y, Z)$  are defined as  $(kX, kY, kZ, k)$ , where  $k$  is an arbitrary, nonzero constant. Clearly, conversion of homogeneous coordinates back to Cartesian coordinates is accomplished by dividing the first three homogeneous coordinates by the fourth. A point in the Cartesian world coordinate system may be expressed in vector form as

$$w = \begin{bmatrix} X \\ Y \\ Z \end{bmatrix}$$

and its homogeneous counterpart is

$$w_h = \begin{bmatrix} kX \\ kY \\ kZ \\ k \end{bmatrix}$$

If we define the perspective transformation matrix as

$$P = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & \frac{-1}{\lambda} & 1 \end{bmatrix}$$

The product  $Pw_h$  yields a vector denoted  $c_h$

$$\begin{aligned} c_h &= Pw_h \\ &= \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & \frac{-1}{\lambda} & 1 \end{bmatrix} \begin{bmatrix} kX \\ kY \\ kZ \\ k \end{bmatrix} \\ &= \begin{bmatrix} kX \\ kY \\ kZ \\ kX - kZ \end{bmatrix} \end{aligned}$$

The element of  $c_h$  is the camera coordinates in homogeneous form. As indicated, these coordinates can be converted to Cartesian form by dividing each of the first three components of  $c_h$  by the fourth. Thus the Cartesian of any point in the camera coordinate system are given in vector form by

$$c = \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} \frac{\lambda X}{\lambda - Z} \\ \frac{\lambda Y}{\lambda - Z} \\ \frac{\lambda Z}{\lambda - Z} \end{bmatrix}$$

The first two components of  $c$  are the  $(x, y)$  coordinates in the image plane of a projected 3 -D point  $(X, Y, Z)$ . The third component is of no interest in terms of the model in Fig. 10. As shown next, this component acts as a free variable in the inverse perspective transformation. The inverse perspective transformation maps an image point back into 3-D.

$$w_h = P^{-1}c_h$$

Where  $P^{-1}$  is

$$P^{-1} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & \frac{1}{\lambda} & 1 \end{bmatrix}$$

Suppose that an image point has coordinates  $(x_o, y_o, 0)$ , where the 0 in the  $z$  location simply indicates that the image plane is located at  $z = 0$ . This point may be expressed in homogeneous

vector form as

$$c_h = \begin{bmatrix} kx_0 \\ ky_0 \\ 0 \\ k \end{bmatrix}$$

$$w_h = \begin{bmatrix} kx_0 \\ ky_0 \\ 0 \\ k \end{bmatrix}$$

or, in Cartesian coordinates

$$w = \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \begin{bmatrix} x_0 \\ y_0 \\ 0 \end{bmatrix}$$

This result obviously is unexpected because it gives  $Z = 0$  for any 3-D point. The problem here is caused by mapping a 3-D scene onto the image plane, which is a many-to-one transformation. The image point  $(x_0, y_0)$  corresponds to the set of collinear 3-D points that lie on the line passing through  $(x_0, y_0, 0)$  and  $(0, 0, \lambda)$ . The equation of this line in the world coordinate system; that is,

$$X = \frac{x_0}{\lambda} (\lambda - Z)$$

$$Y = \frac{y_0}{\lambda} (\lambda - Z).$$

Equations above show that unless something is known about the 3-D point that generated an image point (for example, its  $Z$  coordinate) it is not possible to completely recover the 3-D point from its image. This observation, which certainly is not unexpected, can be used to formulate the

inverse perspective transformation by using the  $z$  component of  $c_h$  as a free variable instead of 0. Thus, by letting

$$c_h = \begin{bmatrix} kx_0 \\ ky_0 \\ kz \\ k \end{bmatrix}$$

It thus follows

$$w_h = \begin{bmatrix} kx_0 \\ ky_0 \\ kz \\ \frac{kz}{\lambda} + k \end{bmatrix}$$

which upon conversion to Cartesian coordinate gives

$$w = \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \begin{bmatrix} \frac{\lambda x_0}{\lambda + z} \\ \frac{\lambda y_0}{\lambda + z} \\ \frac{\lambda z}{\lambda + z} \end{bmatrix}$$

In other words, treating  $z$  as a free variable yields the equations

$$\begin{aligned} X &= \frac{\lambda x_0}{\lambda + z} \\ Y &= \frac{\lambda y_0}{\lambda + z} \\ Z &= \frac{\lambda z}{\lambda + z} \end{aligned}$$

Solving for  $z$  in terms of  $Z$  in the last equation and substituting in the first two expressions yields

$$X = \frac{x_0}{\lambda} (\lambda - Z)$$

$$Y = \frac{y_0}{\lambda} (\lambda - Z)$$

which agrees with the observation that revering a 3-D point from its image by means of the inverse perspective transformation requires knowledge of at least one of the world coordinates of the point.

**1. What is meant by image enhancement by point processing? Discuss any two methods in it.****Basic Gray Level Transformations:**

The study of image enhancement techniques is done by discussing gray-level transformation functions. These are among the simplest of all image enhancement techniques. The values of pixels, before and after processing, will be denoted by  $r$  and  $s$ , respectively. As indicated in the previous section, these values are related by an expression of the form  $s=T(r)$ , where  $T$  is a transformation that maps a pixel value  $r$  into a pixel value  $s$ . Since we are dealing with digital quantities, values of the transformation function typically are stored in a one-dimensional array and the mappings from  $r$  to  $s$  are implemented via table lookups. For an 8-bit environment, a lookup table containing the values of  $T$  will have 256 entries. As an introduction to gray-level transformations, consider Fig. 1.1, which shows three basic types of functions used frequently for image enhancement: linear (negative and identity transformations), logarithmic (log and inverse-log transformations), and power-law (nth power and nth root transformations). The identity function is the trivial case in which output intensities are identical to input intensities. It is included in the graph only for completeness.

**Image Negatives:**

The negative of an image with gray levels in the range  $[0, L-1]$  is obtained by using the negative transformation shown in Fig.1.1, which is given by the expression

$$s = L - 1 - r.$$

Reversing the intensity levels of an image in this manner produces the equivalent of a photographic negative. This type of processing is particularly suited for enhancing white or gray detail embedded in dark regions of an image, especially when the black areas are dominant in size.

**Fig.1.1 Some basic gray-level transformation functions used for image enhancement**

**Log Transformations:**

The general form of the log transformation shown in Fig.1.1 is

$$s = c \log(1 + r)$$

where  $c$  is a constant, and it is assumed that  $r \geq 0$ . The shape of the log curve in Fig. 1.1 shows that this transformation maps a narrow range of low gray-level values in the input image into a wider range of output levels. The opposite is true of higher values of input levels. We would use a transformation of this type to expand the values of dark pixels in an image while compressing the higher-level values. The opposite is true of the inverse log transformation.

Any curve having the general shape of the log functions shown in Fig. 1.1 would accomplish this spreading/compressing of gray levels in an image. In fact, the power-law transformations discussed in the next section are much more versatile for this purpose than the log transformation. However, the log function has the important characteristic that it compresses the dynamic range of images with large variations in pixel values. A classic illustration of an application in which pixel values have a large dynamic range is the Fourier spectrum. At the moment, we are concerned only with the image characteristics of spectra. It is not unusual to encounter spectrum values that range from 0 to or higher. While processing numbers such as these presents no problems for a computer, image display systems generally will not be able to reproduce faithfully such a wide range of intensity values. The net effect is that a significant degree of detail will be lost in the display of a typical Fourier spectrum.

### Power-Law Transformations:

Power-law transformations have the basic form

$$s = cr^\gamma$$

where  $c$  and  $g$  are positive constants. Sometimes Eq. is written as  $s = c(r + \epsilon)^\gamma$

to account for an offset (that is, a measurable output when the input is zero). However, offsets typically are an issue of display calibration and as a result they are normally ignored in Eq. Plots of  $s$  versus  $r$  for various values of  $g$  are shown in Fig. 1.2. As in the case of the log transformation, power-law curves with fractional values of  $g$  map a narrow range of dark input values into a wider range of output values, with the opposite being true for higher values of input levels. Unlike the log function, however, we notice here a family of possible transformation curves obtained simply by varying  $\gamma$ . As expected, we see in Fig. 1.2 that curves generated with values of  $g > 1$  have exactly the opposite effect as those generated with values of  $g < 1$ . Finally, we note that Eq. reduces to the identity transformation when  $c = \gamma = 1$ . A variety of devices used for image capture, printing, and display respond according to a power law. By convention, the exponent in the power-law equation is referred to as gamma. The process used to correct this power-law response phenomena is called gamma correction. For example, cathode ray tube (CRT) devices have an intensity-to-voltage response that is a power function, with exponents varying from approximately 1.8 to 2.5. With reference to the curve for  $g=2.5$  in Fig. 1.2, we see that such display systems would tend to produce images that are darker than intended.

Fig.1.2 Plots of the equation  $s = cr^\gamma$  for various values of  $\gamma$  ( $c=1$  in all cases).

### Piecewise-Linear Transformation Functions:

The principal advantage of piecewise linear functions over the types of functions we have discussed above is that the form of piecewise functions can be arbitrarily complex. In fact, as we will see shortly, a practical implementation of some important transformations can be formulated only as piecewise functions. The principal disadvantage of piecewise functions is that their specification requires considerably more user input.

### Contrast stretching:

One of the simplest piecewise linear functions is a contrast-stretching transformation. Low-contrast images can result from poor illumination, lack of dynamic range in the imaging sensor, or even wrong setting of a lens aperture during image acquisition. The idea behind contrast stretching is to increase the dynamic range of the gray levels in the image being processed.

Figure 1.3 (a) shows a typical transformation used for contrast stretching.

**Fig.1.3 Contrast Stretching (a) Form of Transformation function (b) A low-contrast image (c) Result of contrast stretching (d) Result of thresholding.**

The locations of points  $(r_1, s_1)$  and  $(r_2, s_2)$  control the shape of the transformation function. If  $r_1=s_1$  and  $r_2=s_2$ , the transformation is a linear function that produces no changes in gray levels. If  $r_1=r_2, s_1=0$  and  $s_2=L-1$ , the transformation becomes a thresholding function that creates a binary image, as illustrated in Fig. 1.3 (b). Intermediate values of  $(r_1, s_1)$  and  $(r_2, s_2)$  produce various degrees of spread in the gray levels of the output image, thus affecting its contrast. In general,  $r_1 \leq r_2$  and  $s_1 \leq s_2$  is assumed so that the function is single valued and monotonically increasing. This condition preserves the order of gray levels, thus preventing the creation of intensity artifacts in the processed image.

Figure 1.3 (b) shows an 8-bit image with low contrast. Fig. 1.3(c) shows the result of contrast stretching, obtained by setting  $(r_1, s_1) = (r_{\min}, 0)$  and  $(r_2, s_2) = (r_{\max}, L-1)$  where  $r_{\min}$  and  $r_{\max}$  denote the minimum and maximum gray levels in the image, respectively. Thus, the transformation function stretched the levels linearly from their original range to the full range  $[0,$

L-1]. Finally, Fig. 1.3 (d) shows the result of using the thresholding function defined previously, with  $r_1 = r_2 = m$ , the mean gray level in the image. The original image on which these results are based is a scanning electron microscope image of pollen, magnified approximately 700 times.

**Gray-level slicing:**

Highlighting a specific range of gray levels in an image often is desired. Applications include enhancing features such as masses of water in satellite imagery and enhancing flaws in X-ray images. There are several ways of doing level slicing, but most of them are variations of two basic themes. One approach is to display a high value for all gray levels in the range of interest and a low value for all other gray levels. This transformation, shown in Fig. 1.4 (a), produces a binary image. The second approach, based on the transformation shown in Fig. 1.4 (b), brightens the desired range of gray levels but preserves the background and gray-level tonalities in the image. Figure 1.4(c) shows a gray-scale image, and Fig. 1.4 (d) shows the result of using the transformation in Fig. 1.4 (a). Variations of the two transformations shown in Fig. 1.4 are easy to formulate.

**Fig.1.4 (a) This transformation highlights range [A, B] of gray levels and reduce all others to a constant level (b) This transformation highlights range [A, B] but preserves all other levels (c) An image (d) Result of using the transformation in (a).**

**Bit-plane slicing:**

Instead of highlighting gray-level ranges, highlighting the contribution made to total image appearance by specific bits might be desired. Suppose that each pixel in an image is represented by 8 bits. Imagine that the image is composed of eight 1-bit planes, ranging from bit-plane 0 for the least significant bit to bit-plane 7 for the most significant bit. In terms of 8-bit bytes, plane 0 contains all the lowest order bits in the bytes comprising the pixels in the image and plane 7 contains all the high-order bits. Figure 1.5 illustrates these ideas, and Fig. 1.7 shows the various bit planes for the image shown in Fig.1.6 . Note that the higher-order bits (especially the top four) contain the majority of the visually significant data. The other bit planes contribute to more subtle details in the image. Separating a digital image into its bit planes is useful for analyzing the relative importance played by each bit of the image, a process that aids in determining the adequacy of the number of bits used to quantize each pixel.

**Fig.1.5 Bit-plane representation of an 8-bit image.**

In terms of bit-plane extraction for an 8-bit image, it is not difficult to show that the (binary) image for bit-plane 7 can be obtained by processing the input image with a thresholding gray-level transformation function that (1) maps all levels in the image between 0 and 127 to one level (for example, 0); and (2) maps all levels between 129 and 255 to another (for example, 255).

**Fig.1.6 An 8-bit fractal image**

**Fig.1.7** The eight bit planes of the image in Fig.1.6. The number at the bottom, right of each image identifies the bit plane.

## 2. What is the objective of image enhancement. Define spatial domain. Define point processing.

The term spatial domain refers to the aggregate of pixels composing an image. Spatial domain methods are procedures that operate directly on these pixels. Spatial domain processes will be denoted by the expression

$$g(x, y) = T[f(x, y)]$$

where  $f(x, y)$  is the input image,  $g(x, y)$  is the processed image, and  $T$  is an operator on  $f$ , defined over some neighborhood of  $(x, y)$ . In addition,  $T$  can operate on a set of input images, such as performing the pixel-by-pixel sum of  $K$  images for noise reduction.

The principal approach in defining a neighborhood about a point  $(x, y)$  is to use a square or rectangular subimage area centered at  $(x, y)$ , as Fig.2.1 shows. The center of the subimage is moved from pixel to pixel starting, say, at the top left corner. The operator  $T$  is applied at each location  $(x, y)$  to yield the output,  $g$ , at that location. The process utilizes only the pixels in the area of the image spanned by the neighborhood.

**Fig.2.1 A 3\*3 neighborhood about a point (x, y) in an image.**

Although other neighborhood shapes, such as approximations to a circle, sometimes are used, square and rectangular arrays are by far the most predominant because of their ease of implementation. The simplest form of  $T$  is when the neighborhood is of size  $1 \times 1$  (that is, a single pixel). In this case,  $g$  depends only on the value of  $f$  at  $(x, y)$ , and  $T$  becomes a gray-level (also called an intensity or mapping) transformation function of the form

$$s = T(r)$$

where, for simplicity in notation,  $r$  and  $s$  are variables denoting, respectively, the gray level of  $f(x, y)$  and  $g(x, y)$  at any point  $(x, y)$ . For example, if  $T(r)$  has the form shown in Fig. 2.2(a), the effect of this transformation would be to produce an image of higher contrast than the original by darkening the levels below  $m$  and brightening the levels above  $m$  in the original image. In this technique, known as contrast stretching, the values of  $r$  below  $m$  are compressed by the transformation function into a narrow range of  $s$ , toward black. The opposite effect takes place for values of  $r$  above  $m$ . In the limiting case shown in Fig. 2.2(b),  $T(r)$  produces a two-level (binary) image. A mapping of this form is called a thresholding function. Some fairly simple, yet powerful, processing approaches can be formulated with gray-level transformations. Because enhancement at any point in an image depends only on the gray level at that point, techniques in this category often are referred to as point processing.

**Fig.2.2 Graylevel transformation functions for contrast enhancement.**

Larger neighborhoods allow considerably more flexibility. The general approach is to use a function of the values of  $f$  in a predefined neighborhood of  $(x, y)$  to determine the value of  $g$  at  $(x, y)$ . One of the principal approaches in this formulation is based on the use of so-called masks (also referred to as filters, kernels, templates, or windows). Basically, a mask is a small (say,  $3 \times 3$ ) 2-D array, such as the one shown in Fig. 2.1, in which the values of the mask coefficients determine the nature of the process, such as image sharpening.

### 3. Define histogram of a digital image. Explain how histogram is useful in image enhancement?

#### Histogram Processing:

The histogram of a digital image with gray levels in the range  $[0, L-1]$  is a discrete function  $h(r_k) = n_k$ , where  $r_k$  is the  $k$ th gray level and  $n_k$  is the number of pixels in the image having gray level  $r_k$ . It is common practice to normalize a histogram by dividing each of its values by the total number of pixels in the image, denoted by  $n$ . Thus, a normalized histogram is given by

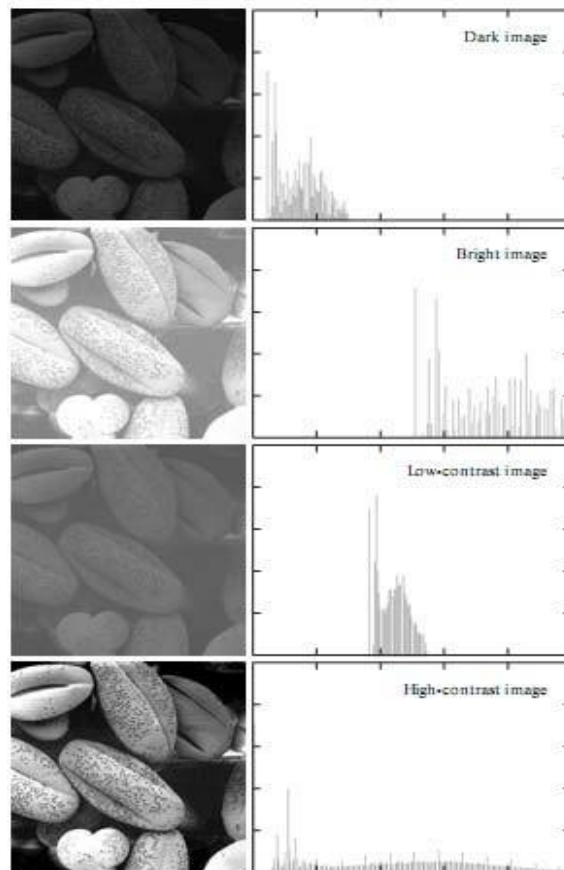

$$p(r_k) = n_k/n$$

for  $k=0,1,\dots,L-1$ . Loosely speaking,  $p(r_k)$  gives an estimate of the probability of occurrence of gray level  $r_k$ . Note that the sum of all components of a normalized histogram is equal to 1.

Histograms are the basis for numerous spatial domain processing techniques. Histogram manipulation can be used effectively for image enhancement. Histograms are simple to calculate in software and also lend themselves to economic hardware implementations, thus making them a popular tool for real-time image processing.

As an introduction to the role of histogram processing in image enhancement, consider Fig. 3, which is the pollen image shown in four basic gray-level characteristics: dark, light, low contrast, and high contrast. The right side of the figure shows the histograms corresponding to these images. The horizontal axis of each histogram plot corresponds to gray level values,  $r_k$ .

The vertical axis corresponds to values of  $h(r_k) = n_k$  or  $p(r_k) = n_k/n$  if the values are normalized. Thus, as indicated previously, these histogram plots are simply plots of  $h(r_k) = n_k$  versus  $r_k$  or  $p(r_k) = n_k/n$  versus  $r_k$ .

**Fig.3 Four basic image types: dark, light, low contrast, high contrast, and their corresponding histograms.**

We note in the dark image that the components of the histogram are concentrated on the low (dark) side of the gray scale. Similarly, the components of the histogram of the bright image are biased toward the high side of the gray scale. An image with low contrast has a histogram that will be narrow and will be centered toward the middle of the gray scale. For a monochrome image this implies a dull, washed-out gray look. Finally, we see that the components of the histogram in the high-contrast image cover a broad range of the gray scale and, further, that the distribution of pixels is not too far from uniform, with very few vertical lines being much higher than the others. Intuitively, it is reasonable to conclude that an image whose pixels tend to occupy the entire range of possible gray levels and, in addition, tend to be distributed uniformly, will have an appearance of high contrast and will exhibit a large variety of gray tones. The net effect will be an image that shows a great deal of gray-level detail and has high dynamic

range. It will be shown shortly that it is possible to develop a transformation function that can automatically achieve this effect, based only on information available in the histogram of the input image.

#### 4. Write about histogram equalization.

##### Histogram Equalization:

Consider for a moment continuous functions, and let the variable  $r$  represent the gray levels of the image to be enhanced. We assume that  $r$  has been normalized to the interval  $[0, 1]$ , with  $r=0$  representing black and  $r=1$  representing white. Later, we consider a discrete formulation and allow pixel values to be in the interval  $[0, L-1]$ . For any  $r$  satisfying the aforementioned conditions, we focus attention on transformations of the form

$$s = T(r) \quad 0 \leq r \leq 1$$

that produce a level  $s$  for every pixel value  $r$  in the original image. For reasons that will become obvious shortly, we assume that the transformation function  $T(r)$  satisfies the following conditions:

- (a)  $T(r)$  is single-valued and monotonically increasing in the interval  $0 \leq r \leq 1$ ; and
- (b)  $0 \leq T(r) \leq 1$  for  $0 \leq r \leq 1$ .

The requirement in (a) that  $T(r)$  be single valued is needed to guarantee that the inverse transformation will exist, and the monotonicity condition preserves the increasing order from black to white in the output image. A transformation function that is not monotonically increasing could result in at least a section of the intensity range being inverted, thus producing some inverted gray levels in the output image. Finally, condition (b) guarantees that the output gray levels will be in the same range as the input levels. Figure 4.1 gives an example of a transformation function that satisfies these two conditions. The inverse transformation from  $s$  back to  $r$  is denoted

$$r = T^{-1}(s) \quad 0 \leq s \leq 1.$$

It can be shown by example that even if  $T(r)$  satisfies conditions (a) and (b), it is possible that the corresponding inverse  $T^{-1}(s)$  may fail to be single valued.

Fig.4.1 A gray-level transformation function that is both single valued and monotonically increasing.

The gray levels in an image may be viewed as random variables in the interval  $[0, 1]$ . One of the most fundamental descriptors of a random variable is its probability density function (PDF). Let  $p_r(r)$  and  $p_s(s)$  denote the probability density functions of random variables  $r$  and  $s$ , respectively, where the subscripts on  $p$  are used to denote that  $p_r$  and  $p_s$  are different functions. A basic result from an elementary probability theory is that, if  $p_r(r)$  and  $T(r)$  are known and  $T^{-1}(s)$  satisfies condition (a), then the probability density function  $p_s(s)$  of the transformed variable  $s$  can be obtained using a rather simple formula:

$$p_s(s) = p_r(r) \left| \frac{dr}{ds} \right|.$$

Thus, the probability density function of the transformed variable,  $s$ , is determined by the gray-level PDF of the input image and by the chosen transformation function. A transformation function of particular importance in image processing has the form

$$s = T(r) = \int_0^r p_r(w) dw$$

where  $w$  is a dummy variable of integration. The right side of Eq. above is recognized as the cumulative distribution function (CDF) of random variable  $r$ . Since probability density functions are always positive, and recalling that the integral of a function is the area under the function, it follows that this transformation function is single valued and monotonically increasing, and, therefore, satisfies condition (a). Similarly, the integral of a probability density function for variables in the range  $[0, 1]$  also is in the range  $[0, 1]$ , so condition (b) is satisfied as well.

Given transformation function  $T(r)$ , we find  $p_s(s)$  by applying Eq. We know from basic calculus (Leibniz's rule) that the derivative of a definite integral with respect to its upper limit is simply the integrand evaluated at that limit. In other words,

$$\begin{aligned} \frac{ds}{dr} &= \frac{dT(r)}{dr} \\ &= \frac{d}{dr} \left[ \int_0^r p_r(w) dw \right] \\ &= p_r(r). \end{aligned}$$

Substituting this result for  $dr/ds$ , and keeping in mind that all probability values are positive, yields

$$\begin{aligned} p_s(s) &= p_r(r) \left| \frac{dr}{ds} \right| \\ &= p_r(r) \left| \frac{1}{p_r(r)} \right| \\ &= 1 \quad 0 \leq s \leq 1. \end{aligned}$$

Because  $p_s(s)$  is a probability density function, it follows that it must be zero outside the interval  $[0, 1]$  in this case because its integral over all values of  $s$  must equal 1. We recognize the form of  $p_s(s)$  as a uniform probability density function. Simply stated, we have demonstrated that performing the transformation function yields a random variable  $s$  characterized by a uniform probability density function. It is important to note from Eq. discussed above that  $T(r)$  depends on  $p_r(r)$ , but, as indicated by Eq. after it, the resulting  $p_s(s)$  always is uniform, independent of the form of  $p_r(r)$ . For discrete values we deal with probabilities and summations instead of probability density functions and integrals. The probability of occurrence of gray level  $r$  in an image is approximated by

$$p_r(r_k) = \frac{n_k}{n} \quad k = 0, 1, 2, \dots, L - 1$$

where, as noted at the beginning of this section,  $n$  is the total number of pixels in the image,  $n_k$  is the number of pixels that have gray level  $r_k$ , and  $L$  is the total number of possible gray levels in the image. The discrete version of the transformation function given in Eq. is

$$\begin{aligned} s_k &= T(r_k) = \sum_{j=0}^k p_r(r_j) \\ &= \sum_{j=0}^k \frac{n_j}{n} \quad k = 0, 1, 2, \dots, L - 1. \end{aligned}$$

Thus, a processed (output) image is obtained by mapping each pixel with level  $r_k$  in the input image into a corresponding pixel with level  $s_k$  in the output image. As indicated earlier, a plot of  $p_r(r_k)$  versus  $r_k$  is called a histogram. The transformation (mapping) is called histogram equalization or histogram linearization. It is not difficult to show that the transformation in Eq. satisfies conditions (a) and (b) stated previously. Unlike its continuous counterpart, it cannot be proved in general that this discrete transformation will produce the discrete equivalent of a uniform probability density function, which would be a uniform histogram.

Fig.4.2 (a) Images from Fig.3 (b) Results of histogram equalization. (c) Corresponding histograms.

The inverse transformation from  $s$  back to  $r$  is denoted by

$$r_k = T^{-1}(s_k) \quad k = 0, 1, 2, \dots, L - 1$$

## 5. Write about histogram specification.

### Histogram Matching (Specification):

Histogram equalization automatically determines a transformation function that seeks to produce an output image that has a uniform histogram. When automatic enhancement is desired, this is a good approach because the results from this technique are predictable and the method is simple to implement. In particular, it is useful sometimes to be able to specify the shape of the histogram that we wish the processed image to have. The method used to generate a processed image that has a specified histogram is called histogram matching or histogram specification.

### Development of the method:

Let us return for a moment to continuous gray levels  $r$  and  $z$  (considered continuous random variables), and let  $p_r(r)$  and  $p_z(z)$  denote their corresponding continuous probability density functions. In this notation,  $r$  and  $z$  denote the gray levels of the input and output (processed) images, respectively. We can estimate  $p_r(r)$  from the given input image, while  $p_z(z)$  is the specified probability density function that we wish the output image to have.

Let  $s$  be a random variable with the property

$$s = T(r) = \int_0^r p_r(w) dw$$

where  $w$  is a dummy variable of integration. We recognize this expression as the continuous version of histogram equalization. Suppose next that we define a random variable  $z$  with the property

$$G(z) = \int_0^z p_z(t) dt = s$$

where  $t$  is a dummy variable of integration. It then follows from these two equations that  $G(z)=T(r)$  and, therefore, that  $z$  must satisfy the condition

$$z = G^{-1}(s) = G^{-1}[T(r)].$$

The transformation  $T(r)$  can be obtained once  $p_r(r)$  has been estimated from the input image. Similarly, the transformation function  $G(z)$  can be obtained because  $p_z(z)$  is given. Assuming that  $G^{-1}$  exists and that it satisfies conditions (a) and (b) in the histogram equalization process, the above three equations show that an image with a specified probability density function can be obtained from an input image by using the following procedure:

- (1) Obtain the transformation function  $T(r)$ .
- (2) To obtain the transformation function  $G(z)$ .
- (3) Obtain the inverse transformation function  $G^{-1}$
- (4) Obtain the output image by applying above Eq. to all the pixels in the input image.

The result of this procedure will be an image whose gray levels,  $z$ , have the specified probability density function  $p_z(z)$ . Although the procedure just described is straightforward in principle, it is seldom possible in practice to obtain analytical expressions for  $T(r)$  and for  $G^{-1}$ . Fortunately, this problem is simplified considerably in the case of discrete values. The price we pay is the same as in histogram equalization, where only an approximation to the desired histogram is achievable. In spite of this, however, some very useful results can be obtained even with crude approximations.

$$\begin{aligned} s_k &= T(r_k) = \sum_{j=0}^k p_r(r_j) \\ &= \sum_{j=0}^k \frac{n_j}{n} \quad k = 0, 1, 2, \dots, L - 1 \end{aligned}$$

where  $n$  is the total number of pixels in the image,  $n_j$  is the number of pixels with gray level  $r_j$ , and  $L$  is the number of discrete gray levels. Similarly, the discrete formulation is obtained from the given histogram  $p_z(z_i)$ ,  $i=0, 1, 2, \dots, L-1$ , and has the form

$$v_k = G(z_k) = \sum_{i=0}^k p_z(z_i) = s_k \quad k = 0, 1, 2, \dots, L - 1.$$

As in the continuous case, we are seeking values of  $z$  that satisfy this equation. The variable  $v_k$  was added here for clarity in the discussion that follows. Finally, the discrete version of the above Eqn. is given by

$$z_k = G^{-1}[T(r_k)] \quad k = 0, 1, 2, \dots, L - 1$$

Or

$$z_k = G^{-1}(s_k) \quad k = 0, 1, 2, \dots, L - 1.$$

### Implementation:

We start by noting the following: (1) Each set of gray levels  $\{r_j\}$ ,  $\{s_j\}$ , and  $\{z_j\}$ ,  $j=0, 1, 2, \dots, L-1$ , is a one-dimensional array of dimension  $L \times 1$ . (2) All mappings from  $r$  to  $s$  and from  $s$  to  $z$  are simple table lookups between a given pixel value and these arrays. (3) Each of the elements of these arrays, for example,  $s_k$ , contains two important pieces of information: The subscript  $k$  denotes the location of the element in the array, and  $s$  denotes the value at that location. (4) We need to be concerned only with integer pixel values. For example, in the case of an 8-bit image,  $L=256$  and the elements of each of the arrays just mentioned are integers between 0 and 255. This implies that we now work with gray level values in the interval  $[0, L-1]$  instead of the normalized interval  $[0, 1]$  that we used before to simplify the development of histogram processing techniques.

In order to see how histogram matching actually can be implemented, consider Fig. 5(a), ignoring for a moment the connection shown between this figure and Fig. 5(c). Figure 5(a) shows a hypothetical discrete transformation function  $s=T(r)$  obtained from a given image. The first gray level in the image,  $r_1$ , maps to  $s_1$ ; the second gray level,  $r_2$ , maps to  $s_2$ ; the  $k$ th level  $r_k$  maps to  $s_k$ ; and so on (the important point here is the ordered correspondence between these values). Each value  $s_j$  in the array is precomputed, so the process of mapping simply uses the actual value of a pixel as an index in an array to determine the corresponding value of  $s$ . This process is particularly easy because we are dealing with integers. For example, the  $s$  mapping for an 8-bit pixel with value 127 would be found in the 128th position in array  $\{s_j\}$  (recall that we start at 0) out of the possible 256 positions. If we stopped here and mapped the value of each pixel of an input image by the

**Fig.5. (a) Graphical interpretation of mapping from  $r_k$  to  $s_k$  via  $T(r)$ . (b) Mapping of  $z_q$  to its corresponding value  $v_q$  via  $G(z)$  (c) Inverse mapping from  $s_k$  to its corresponding value of  $z_k$ .**

method just described, the output would be a histogram-equalized image. In order to implement histogram matching we have to go one step further. Figure 5(b) is a hypothetical transformation function  $G$  obtained from a given histogram  $p_z(z)$ . For any  $z_q$ , this transformation function yields a corresponding value  $v_q$ . This mapping is shown by the arrows in Fig. 5(b). Conversely, given any value  $v_q$ , we would find the corresponding value  $z_q$  from  $G^{-1}$ . In terms of the figure, all this means graphically is that we would reverse the direction of the arrows to map  $v_q$  into its corresponding  $z_q$ . However, we know from the definition that  $v=s$  for corresponding subscripts, so we can use exactly this process to find the  $z_k$  corresponding to any value  $s_k$  that we computed previously from the equation  $s_k = T(r_k)$ . This idea is shown in Fig.5(c).

Since we really do not have the  $z$ 's (recall that finding these values is precisely the objective of histogram matching), we must resort to some sort of iterative scheme to find  $z$  from  $s$ . The fact that we are dealing with integers makes this a particularly simple process. Basically, because  $v_k = s_k$ , we have that the  $z$ 's for which we are looking must satisfy the equation  $G(z_k) = s_k$ , or  $(G(z_k) - s_k) = 0$ . Thus, all we have to do to find the value of  $z_k$  corresponding to  $s_k$  is to iterate on values of  $z$  such that this equation is satisfied for  $k=0,1,2,\dots,L-1$ . We do not have to find the inverse of  $G$  because we are going to iterate on  $z$ . Since we are dealing with integers, the closest we can get to satisfying the equation  $(G(z_k) - s_k) = 0$  is to let  $z_k = \hat{z}$  for each value of  $k$ , where  $\hat{z}$  is the smallest integer in the interval  $[0, L-1]$  such that

$$(G(\hat{z}) - s_k) \geq 0 \quad k = 0, 1, 2, \dots, L - 1.$$

Given a value  $s_k$ , all this means conceptually in terms of Fig. 5(c) is that we would start with and increase it in integer steps until Eq. 5.10 is satisfied, at which point we let repeating this process for all values of  $k$  would yield all the required mappings from  $s$  to  $z$ , which constitutes the implementation of Eq. 5.10. In practice, we would not have to start with each time because the values of  $s_k$  are known to increase monotonically. Thus, for  $k=k+1$ , we would start with  $\hat{z} = z_k$  and increment in integer values from there.

## 6. Write about Local enhancement.

### Local Enhancement:

The histogram processing methods discussed in the previous two sections are global, in the sense that pixels are modified by a transformation function based on the gray-level content of an entire image. Although this global approach is suitable for overall enhancement, there are cases in which it is necessary to enhance details over small areas in an image. The number of pixels in these areas may have negligible influence on the computation of a global transformation whose shape does not necessarily guarantee the desired local enhancement. The solution is to devise transformation functions based on the gray-level distribution—or other properties—in the neighborhood of every pixel in the image.

The histogram processing techniques are easily adaptable to local enhancement. The procedure is to define a square or rectangular neighborhood and move the center of this area from pixel to pixel. At each location, the histogram of the points in the neighborhood is computed and either a histogram equalization or histogram specification transformation function is obtained. This function is finally used to map the gray level of the

pixel centered in the neighborhood. The center of the neighborhood region is then moved to an adjacent pixel location and the procedure is repeated. Since only one new row or column of the neighborhood changes during a pixel-to-pixel translation of the region, updating the histogram obtained in the previous location with the new data introduced at each motion step is possible. This approach has obvious advantages over repeatedly computing the histogram over all pixels in the neighborhood region each time the region is moved one pixel location. Another approach used some times to reduce computation is to utilize nonoverlapping regions, but this method usually produces an undesirable checkerboard effect.

## 7. What is meant by image subtraction? Discuss various areas of application of image subtraction.

### Image Subtraction:

The difference between two images  $f(x, y)$  and  $h(x, y)$ , expressed as

$$g(x, y) = f(x, y) - h(x, y),$$

is obtained by computing the difference between all pairs of corresponding pixels from  $f$  and  $h$ . The key usefulness of subtraction is the enhancement of differences between images. The higher-order bit planes of an image carry a significant amount of visually relevant detail, while the lower planes contribute more to fine (often imperceptible) detail. Figure 7(a) shows the fractal image used earlier to illustrate the concept of bit planes. Figure 7(b) shows the result of discarding (setting to zero) the four least significant bit planes of the original image. The images are nearly identical visually, with the exception of a very slight drop in overall contrast due to less variability of the graylevel values in the image of Fig. 7(b). The pixel-by-pixel difference between these two images is shown in Fig. 7(c). The differences in pixel values are so small that the difference image appears nearly black when displayed on an 8-bit display. In order to bring out more detail, we can perform a contrast stretching transformation. We chose histogram equalization, but an appropriate power-law transformation would have done the job also. The result is shown in Fig. 7(d). This is a very useful image for evaluating the effect of setting to zero the lower-order planes.

**Fig.7 (a) Original fractal image (b) Result of setting the four lower-order bit planes to zero (c) Difference between (a) and(b) (d) Histogram equalized difference image.**

One of the most commercially successful and beneficial uses of image subtraction is in the area of medical imaging called mask mode radiography. In this case  $h(x, y)$ , the mask, is an X-ray image of a region of a patient's body captured by an intensified TV camera (instead of traditional X-ray film) located opposite an X-ray source. The procedure consists of injecting a contrast medium into the patient's bloodstream, taking a series of images of the same anatomical region as  $h(x, y)$ , and subtracting this mask from the series of incoming images after injection of the contrast medium. The net effect of subtracting the mask from each sample in the incoming stream of TV images is that the areas that are different between  $f(x, y)$  and  $h(x, y)$  appear in the output image as enhanced detail. Because images can be captured at TV rates, this procedure in essence gives a movie showing how the contrast medium propagates through the various arteries in the area being observed.

## 8. Explain about image averaging process.

### Image Averaging:

Consider a noisy image  $g(x, y)$  formed by the addition of noise  $h(x, y)$  to an original image  $f(x, y)$ ; that is,

$$g(x, y) = f(x, y) + \eta(x, y)$$

where the assumption is that at every pair of coordinates  $(x, y)$  the noise is uncorrelated and has zero average value. The objective of the following procedure is to reduce the noise content by adding a set of noisy images,  $\{g_i(x, y)\}$ . If the noise satisfies the constraints just stated, it can be shown that if an image  $\bar{g}(x, y)$  is formed by averaging  $K$  different noisy images,

$$\bar{g}(x, y) = \frac{1}{K} \sum_{i=1}^K g_i(x, y)$$

Then it follows that

$$E\{\bar{g}(x, y)\} = f(x, y)$$

and

$$\sigma_{\bar{g}(x, y)}^2 = \frac{1}{K} \sigma_{\eta(x, y)}^2$$

Where  $E\{\bar{g}(x, y)\}$  is the expected value of  $\bar{g}$  and  $\sigma_{\bar{g}(x, y)}^2$  and  $\sigma_{\eta(x, y)}^2$  are the variances of  $\bar{g}$  and  $\eta$ , all at coordinates  $(x, y)$ . The standard deviation at any point in the average image is

$$\sigma_{\bar{g}(x, y)} = \frac{1}{\sqrt{K}} \sigma_{\eta(x, y)}$$

As  $K$  increases, the above equations indicate that the variability (noise) of the pixel values at each location  $(x, y)$  decreases. Because  $E\{\bar{g}(x, y)\} = f(x, y)$ , this means that  $\bar{g}(x, y)$  approaches  $f(x, y)$  as the number of noisy images used in the averaging process increases. In practice, the images  $g_i(x, y)$  must be registered (aligned) in order to avoid the introduction of blurring and other artifacts in the output image.

## 9. Discuss about the mechanics of filtering in spatial domain. Mention the points to be considered in implementation neighbourhood operations for spatial filtering.

### Basics of Spatial Filtering:

Some neighborhood operations work with the values of the image pixels in the neighborhood and the corresponding values of a subimage that has the same dimensions as the neighborhood. The subimage is called a filter, mask, kernel, template, or window, with the first three terms being the most prevalent terminology. The values in a filter subimage are referred to as coefficients, rather than pixels. The concept of filtering has its roots in the use of the Fourier transform for signal processing in the so-called frequency domain. We use the term spatial filtering to differentiate this type of process from the more traditional frequency domain filtering.

The mechanics of spatial filtering are illustrated in Fig.9.1. The process consists simply of moving the filter mask from point to point in an image. At each point  $(x, y)$ , the response of the filter at that point is calculated using a predefined relationship. The response is given by a sum of products of the filter coefficients and the corresponding image pixels in the area spanned by the filter mask. For the  $3 \times 3$  mask shown in Fig. 9.1, the result (or response),  $R$ , of linear filtering with the filter mask at a point  $(x, y)$  in the image is

$$R = w(-1, -1)f(x - 1, y - 1) + w(-1, 0)f(x - 1, y) + \dots \\ + w(0, 0)f(x, y) + \dots + w(1, 0)f(x + 1, y) + w(1, 1)f(x + 1, y + 1),$$

which we see is the sum of products of the mask coefficients with the corresponding pixels directly under the mask. Note in particular that the coefficient  $w(0, 0)$  coincides with image value  $f(x, y)$ , indicating that the mask is centered at  $(x, y)$  when the computation of the sum of products takes place. For a mask of size  $m \times n$ , we assume that  $m=2a+1$  and  $n=2b+1$ , where  $a$  and  $b$  are nonnegative integers.

**Fig.9.1** The mechanics of spatial filtering. The magnified drawing shows a 3X3 mask and the image section directly under it; the image section is shown displaced out from under the mask for ease of readability.

In general, linear filtering of an image  $f$  of size  $M \times N$  with a filter mask of size  $m \times n$  is given by the expression:

$$g(x, y) = \sum_{s=-a}^a \sum_{t=-b}^b w(s, t) f(x + s, y + t)$$

where, from the previous paragraph,  $a=(m-1)/2$  and  $b=(n-1)/2$ .

To generate a complete filtered image this equation must be applied for  $x=0,1,2,\dots, M-1$  and  $y=0,1,2,\dots, N-1$ . In this way, we are assured that the mask processes all pixels in the image. It is easily verified when  $m=n=3$  that this expression reduces to the example given in the previous paragraph.

The process of linear filtering is similar to a frequency domain concept called convolution. For this reason, linear spatial filtering often is referred to as “convolving a mask with an image.” Similarly, filter masks are sometimes called convolution masks. The term convolution kernel also is in common use. When interest lies on the response,  $R$ , of an  $m \times n$  mask at any point  $(x,y)$ , and not on the mechanics of implementing mask convolution, it is common practice to simplify the notation by using the following expression:

$$\begin{aligned} R &= w_1 z_1 + w_2 z_2 + \dots + w_{mn} z_{mn} \\ &= \sum_{i=1}^{mn} w_i z_i \end{aligned}$$

where the  $w$ 's are mask coefficients, the  $z$ 's are the values of the image graylevels corresponding to those coefficients, and  $mn$  is the total number of coefficients in the mask. For the  $3 \times 3$  general mask shown in Fig.9.2 the response at any point  $(x, y)$  in the image is given by

$$\begin{aligned} R &= w_1 z_1 + w_2 z_2 + \dots + w_9 z_9 \\ &= \sum_{i=1}^9 w_i z_i. \end{aligned}$$

$w_1$	$w_2$	$w_3$
$w_4$	$w_5$	$w_6$
$w_7$	$w_8$	$w_9$

**Fig.9.2 Another representation of a general 3 x 3 spatial filter mask.**

An important consideration in implementing neighborhood operations for spatial filtering is the issue of what happens when the center of the filter approaches the border of the image. Consider for simplicity a square mask of size  $n \times n$ . At least one edge of such a mask will coincide with the border of the image when the center of the mask is at a distance of  $(n-1)/2$  pixels away from the border of the image. If the center of the mask moves any closer to the border, one or more rows or columns of the mask will be located outside the image plane. There are several ways to handle this situation. The simplest is to limit the excursions of the center of the mask to be at a distance no less than  $(n-1)/2$  pixels from the border. The resulting filtered image will be smaller than the original, but all the pixels in the filtered image will have been processed with the full mask. If the result is required to be the same size as the original, then the approach typically employed is to filter all pixels only with the section of the mask that is fully contained in the image. With this approach, there will be bands of pixels near the border that will have been processed with a partial filter mask. Other approaches include “padding” the image by adding rows and columns of 0’s (or other constant gray level), or padding by replicating rows or columns. The padding is then stripped off at the end of the process.

This keeps the size of the filtered image the same as the original, but the values of the padding will have an effect near the edges that becomes more prevalent as the size of the mask increases. The only way to obtain a perfectly filtered result is to accept a somewhat smaller filtered image by limiting the excursions of the center of the filter mask to a distance no less than  $(n-1)/2$  pixels from the border of the original image.

## **10. Write about Smoothing Spatial filters.**

### **Smoothing Spatial Filters:**

Smoothing filters are used for blurring and for noise reduction. Blurring is used in preprocessing steps, such as removal of small details from an image prior to (large) object extraction, and bridging of small gaps in lines or curves. Noise reduction can be accomplished by blurring with a linear filter and also by non-linear filtering.

#### **(1) Smoothing Linear Filters:**

The output (response) of a smoothing, linear spatial filter is simply the average of the pixels contained in the neighborhood of the filter mask. These filters sometimes are called averaging filters. The idea behind smoothing filters is straightforward. By replacing the value of every pixel

in an image by the average of the gray levels in the neighborhood defined by the filter mask, this process results in an image with reduced “sharp” transitions in gray levels. Because random noise typically consists of sharp transitions in gray levels, the most obvious application of smoothing is noise reduction. However, edges (which almost always are desirable features of an image) also are characterized by sharp transitions in gray levels, so averaging filters have the undesirable side effect that they blur edges. Another application of this type of process includes the smoothing of false contours that result from using an insufficient number of gray levels.

$$\frac{1}{9} \times \begin{array}{|c|c|c|} \hline 1 & 1 & 1 \\ \hline 1 & 1 & 1 \\ \hline 1 & 1 & 1 \\ \hline \end{array} \quad \frac{1}{16} \times \begin{array}{|c|c|c|} \hline 1 & 2 & 1 \\ \hline 2 & 4 & 2 \\ \hline 1 & 2 & 1 \\ \hline \end{array}$$

**Fig.10.1 Two 3 x 3 smoothing (averaging) filter masks. The constant multiplier in front of each mask is equal to the sum of the values of its coefficients, as is required to compute an average.**

A major use of averaging filters is in the reduction of “irrelevant” detail in an image. By “irrelevant” we mean pixel regions that are small with respect to the size of the filter mask.

Figure 10.1 shows two 3 x 3 smoothing filters. Use of the first filter yields the standard average of the pixels under the mask. This can best be seen by substituting the coefficients of the mask in

$$R = \frac{1}{9} \sum_{i=1}^9 z_i,$$

which is the average of the gray levels of the pixels in the 3 x 3 neighborhood defined by the mask. Note that, instead of being 1/9, the coefficients of the filter are all 1's. The idea here is that it is computationally more efficient to have coefficients valued 1. At the end of the filtering process the entire image is divided by 9. An m x n mask would have a normalizing constant equal to 1/mn.

A spatial averaging filter in which all coefficients are equal is sometimes called a box filter.

The second mask shown in Fig.10.1 is a little more interesting. This mask yields a so-called weighted average, terminology used to indicate that pixels are multiplied by different coefficients, thus giving more importance (weight) to some pixels at the expense of others. In the mask shown in Fig. 10.1(b) the pixel at the center of the mask is multiplied by a higher value than any other, thus giving this pixel more importance in the calculation of the average. The other pixels are inversely weighted as a function of their distance from the center of the mask. The diagonal terms are further away from the center than the orthogonal neighbors (by a factor of  $\sqrt{2}$ ) and, thus, are weighed less than these immediate neighbors of the center pixel. The basic strategy behind weighing the center point the highest and then reducing the value of the coefficients as a function of increasing distance from the origin is simply an attempt to reduce blurring in the smoothing process. We could have picked other weights to accomplish the same general objective. However, the sum of all the coefficients in the mask of Fig. 10.1(b) is equal to 16, an attractive feature for computer implementation because it has an integer power of 2. In practice, it is difficult in general to see differences between images smoothed by using either of the masks in Fig. 10.1, or similar arrangements, because the area these masks span at any one location in an image is so small.

The general implementation for filtering an  $M \times N$  image with a weighted averaging filter of size  $m \times n$  ( $m$  and  $n$  odd) is given by the expression

$$g(x, y) = \frac{\sum_{s=-a}^a \sum_{t=-b}^b w(s, t) f(x + s, y + t)}{\sum_{s=-a}^a \sum_{t=-b}^b w(s, t)}$$

## 2.Order-Statistics Filters:

Order-statistics filters are nonlinear spatial filters whose response is based on ordering (ranking) the pixels contained in the image area encompassed by the filter, and then replacing the value of the center pixel with the value determined by the ranking result. The best-known example in this category is the median filter, which, as its name implies, replaces the value of a pixel by the median of the gray levels in the neighborhood of that pixel (the original value of the pixel is included in the computation of the median). Median filters are quite popular because, for certain types of random noise, they provide excellent noise-reduction capabilities, with considerably less blurring than linear smoothing filters of similar size. Median filters are particularly effective in the presence of impulse noise, also called salt-and-pepper noise because of its appearance as white and black dots superimposed on an image.

The median,  $\varepsilon$ , of a set of values is such that half the values in the set are less than or equal to  $\varepsilon$ , and half are greater than or equal to  $\varepsilon$ . In order to perform median filtering at a point in an image, we first sort the values of the pixel in question and its neighbors, determine their median, and

assign this value to that pixel. For example, in a 3 x 3 neighborhood the median is the 5th largest value, in a 5 x 5 neighborhood the 13th largest value, and so on. When several values in a neighborhood are the same, all equal values are grouped. For example, suppose that a 3 x 3 neighborhood has values (10, 20, 20, 20, 15, 20, 20, 25, 100). These values are sorted as (10, 15, 20, 20, 20, 20, 20, 25, 100), which results in a median of 20. Thus, the principal function of median filters is to force points with distinct gray levels to be more like their neighbors. In fact, isolated clusters of pixels that are light or dark with respect to their neighbors, and whose area is less than  $n^2 / 2$  (one-half the filter area), are eliminated by an  $n \times n$  median filter. In this case “eliminated” means forced to the median intensity of the neighbors. Larger clusters are affected considerably less.

### 11. What is meant by the Gradient and the Laplacian? Discuss their role in image enhancement.

#### Use of Second Derivatives for Enhancement–The Laplacian:

The approach basically consists of defining a discrete formulation of the second-order derivative and then constructing a filter mask based on that formulation. We are interested in isotropic filters, whose response is independent of the direction of the discontinuities in the image to which the filter is applied. In other words, isotropic filters are rotation invariant, in the sense that rotating the image and then applying the filter gives the same result as applying the filter to the image first and then rotating the result.

#### Development of the method:

It can be shown (Rosenfeld and Kak [1982]) that the simplest isotropic derivative operator is the Laplacian, which, for a function (image)  $f(x, y)$  of two variables, is defined as

$$\nabla^2 f = \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2}.$$

Because derivatives of any order are linear operations, the Laplacian is a linear operator. In order to be useful for digital image processing, this equation needs to be expressed in discrete form. There are several ways to define a digital Laplacian using neighborhoods. digital second. Taking into account that we now have two variables, we use the following notation for the partial second-order derivative in the x-direction:

$$\frac{\partial^2 f}{\partial^2 x^2} = f(x + 1, y) + f(x - 1, y) - 2f(x, y)$$

and, similarly in the y-direction, as

$$\frac{\partial^2 f}{\partial^2 y^2} = f(x, y + 1) + f(x, y - 1) - 2f(x, y)$$

The digital implementation of the two-dimensional Laplacian in Eq. is obtained by summing these two components

$$\nabla^2 f = [f(x + 1, y) + f(x - 1, y) + f(x, y + 1) + f(x, y - 1)] - 4f(x, y). \quad ($$

This equation can be implemented using the mask shown in Fig.11.1(a), which gives an isotropic result for rotations in increments of 90°.

The diagonal directions can be incorporated in the definition of the digital Laplacian by adding two more terms to Eq., one for each of the two diagonal directions. The form of each new term is the same as either Eq.

0	1	0	1	1	1
1	-4	1	1	-8	1
0	1	0	1	1	1
0	-1	0	-1	-1	-1
-1	4	-1	-1	8	-1
0	-1	0	-1	-1	-1

a b  
c d

**Fig.11.1. (a) Filter mask used to implement the digital Laplacian (b) Mask used to implement an extension of this equation that includes the diagonal neighbors. (c) and (d) Two other implementations of the Laplacian.**

but the coordinates are along the diagonals. Since each diagonal term also contains a  $-2f(x, y)$  term, the total subtracted from the difference terms now would be  $-8f(x, y)$ . The mask used to implement this new definition is shown in Fig.11.1(b). This mask yields isotropic results for increments of  $45^\circ$ . The other two masks shown in Fig. 11 also are used frequently in practice.

They are based on a definition of the Laplacian that is the negative of the one we used here. As such, they yield equivalent results, but the difference in sign must be kept in mind when combining (by addition or subtraction) a Laplacian-filtered image with another image.

Because the Laplacian is a derivative operator, its use highlights gray-level discontinuities in an image and deemphasizes regions with slowly varying gray levels. This will tend to produce images that have grayish edge lines and other discontinuities, all superimposed on a dark, featureless background. Background features can be “recovered” while still preserving the sharpening effect of the Laplacian operation simply by adding the original and Laplacian images. As noted in the previous paragraph, it is important to keep in mind which definition of the Laplacian is used. If the definition used has a negative center coefficient, then we subtract, rather than add, the Laplacian image to obtain a sharpened result. Thus, the basic way in which we use the Laplacian for image enhancement is as follows:

$$g(x, y) = \begin{cases} f(x, y) - \nabla^2 f(x, y) & \text{if the center coefficient of the} \\ & \text{Laplacian mask is negative} \\ f(x, y) + \nabla^2 f(x, y) & \text{if the center coefficient of the} \\ & \text{Laplacian mask is positive.} \end{cases}$$

### Use of First Derivatives for Enhancement—The Gradient:

First derivatives in image processing are implemented using the magnitude of the gradient. For a function  $f(x, y)$ , the gradient of  $f$  at coordinates  $(x, y)$  is defined as the two-dimensional column vector

$$\nabla f = \begin{bmatrix} G_x \\ G_y \end{bmatrix} = \begin{bmatrix} \frac{\partial f}{\partial x} \\ \frac{\partial f}{\partial y} \end{bmatrix}.$$

The magnitude of this vector is given by

$$\begin{aligned} \nabla f &= \text{mag}(\nabla \mathbf{f}) \\ &= [G_x^2 + G_y^2]^{1/2} \\ &= \left[ \left( \frac{\partial f}{\partial x} \right)^2 + \left( \frac{\partial f}{\partial y} \right)^2 \right]^{1/2}. \end{aligned}$$

The components of the gradient vector itself are linear operators, but the magnitude of this vector obviously is not because of the squaring and square root operations. On the other hand, the partial derivatives are not rotation invariant (isotropic), but the magnitude of the gradient vector is. Although it is not strictly correct, the magnitude of the gradient vector often is referred to as the gradient.

The computational burden of implementing over an entire image is not trivial, and it is common practice to approximate the magnitude of the gradient by using absolute values instead of squares and square roots:

$$\nabla f \approx |G_x| + |G_y|.$$

This equation is simpler to compute and it still preserves relative changes in gray levels, but the isotropic feature property is lost in general. However, as in the case of the Laplacian, the isotropic properties of the digital gradient defined in the following paragraph are preserved only for a limited number of rotational increments that depend on the masks used to approximate the derivatives. As it turns out, the most popular masks used to approximate the gradient give the same result only for vertical and horizontal edges and thus the isotropic properties of the gradient are preserved only for multiples of  $90^\circ$ .

As in the case of the Laplacian, we now define digital approximations to the preceding equations, and from there formulate the appropriate filter masks. In order to simplify the discussion that follows, we will use the notation in Fig. 11.2 (a) to denote image points in a  $3 \times 3$  region. For example, the center point,  $z_5$ , denotes  $f(x, y)$ ,  $z_1$  denotes  $f(x-1, y-1)$ , and so on. The simplest approximations to a first-order derivative that satisfy the conditions stated in that section are  $G_x = (z_8 - z_5)$  and  $G_y = (z_6 - z_5)$ . Two other definitions proposed by Roberts [1965] in the early development of digital image processing use cross differences:

$$G_x = (z_9 - z_5) \quad \text{and} \quad G_y = (z_8 - z_6).$$

we compute the gradient as

$$\nabla f = [(z_9 - z_5)^2 + (z_8 - z_6)^2]^{1/2}$$

If we use absolute values, then substituting the quantities in the equations gives us the following approximation to the gradient:

$$\nabla f \approx |z_9 - z_5| + |z_8 - z_6|.$$

This equation can be implemented with the two masks shown in Figs. 11.2 (b) and(c). These masks are referred to as the Roberts cross-gradient operators. Masks of even size are awkward to implement. The smallest filter mask in which we are interested is of size 3 x 3. An approximation using absolute values, still at point  $z_5$ , but using a 3\*3 mask, is

$$\nabla f \approx |(z_7 + 2z_8 + z_9) - (z_1 + 2z_2 + z_3)| + |(z_3 + 2z_6 + z_9) - (z_1 + 2z_4 + z_7)|.$$

The difference between the third and first rows of the 3 x 3 image region approximates the derivative in the x-direction, and the difference between the third and first columns approximates the derivative in the y-direction. The masks shown in Figs. 11.2 (d) and (e), called the Sobel operators. The idea behind using a weight value of 2 is to achieve some smoothing by giving more importance to the center point. Note that the coefficients in all the masks shown in Fig. 11.2 sum to 0, indicating that they would give a response of 0 in an area of constant gray level, as expected of a derivative operator.

**Fig.11.2 A 3 x 3 region of an image (the z's are gray-level values) and masks used to**

**compute the gradient at point labeled  $z_5$  . All masks coefficients sum to zero, as expected of a derivative operator.**

## 1. Discuss the frequency domain techniques of image enhancement in detail.

Enhancement In Frequency Domain:

The frequency domain methods of image enhancement are based on convolution theorem. This is represented as,

$$g(x, y) = h(x, y) * f(x, y)$$

Where.

$g(x, y)$  = Resultant image

$h(x, y)$  = Position invariant operator

$f(x, y)$  = Input image

The Fourier transform representation of equation above is,

$$G(u, v) = H(u, v) F(u, v)$$

The function  $H(u, v)$  in equation is called transfer function. It is used to boost the edges of input image  $f(x, y)$  to emphasize the high frequency components.

The different frequency domain methods for image enhancement are as follows.

1. Contrast stretching.
2. Clipping and thresholding.
3. Digital negative.
4. Intensity level slicing and
5. Bit extraction.

### 1. Contrast Stretching:

Due to non-uniform lighting conditions, there may be poor contrast between the background and the feature of interest. Figure 1.1 (a) shows the contrast stretching transformations.

**Fig.1.1 (a) Histogram of input image**

**Fig.1.1 (b) Linear Law**

**Fig.1.1 (c) Histogram of the transformed image**

These stretching transformations are expressed as

In the area of stretching the slope of transformation is considered to be greater than unity. The parameters of stretching transformations i.e.,  $a$  and  $b$  can be determined by examining the histogram of the image.

## 2. Clipping and Thresholding:

Clipping is considered as the special scenario of contrast stretching. It is the case in which the parameters are  $\alpha = \gamma = 0$ . Clipping is more advantageous for reduction of noise in input signals of range  $[a, b]$ .

Threshold of an image is selected by means of its histogram. Let us take the image shown in the following figure 1.2.

Fig. 1.2

The figure 1.2 (b) consists of two peaks i.e., background and object. At the abscissa of histogram minimum ( $D_1$ ) the threshold is selected. This selected threshold ( $D_1$ ) can separate background and object to convert the image into its respective binary form. The thresholding transformations are shown in figure 1.3.

Fig.1.3

### 3. Digital Negative:

The digital negative of an image is achieved by reverse scaling of its grey levels to the transformation. They are much essential in displaying of medical images.

A digital negative transformation of an image is shown in figure 1.4.

Fig.1.4

**4. Intensity Level Slicing:**

The images which consist of grey levels in between intensity at background and other objects require to reduce the intensity of the object. This process of changing intensity level is done with the help of intensity level slicing. They are expressed as

$$V = \begin{cases} L & , \quad a \leq u \leq b \\ 0 & , \quad \text{elsewhere} \end{cases} \quad \text{without background}$$

And

$$V = \begin{cases} L & , \quad a \leq u \leq b \\ u & , \quad \text{elsewhere} \end{cases} \quad \text{with background}$$

The histogram of input image and its respective intensity level slicing is shown in the figure 1.5.

Fig.1.5

When an image is uniformly quantized then, the  $n^{\text{th}}$  most significant bit can be extracted and displayed.

$$\text{Let, } u = k_1 2^{B-1} + k_2 2^{B-2} + \dots + k_{B-1} 2 + k_B$$

Then, the output is expressed as

$$V = \begin{cases} L, & \text{for } k_n = 1 \\ 0, & \text{elsewhere} \end{cases}$$

## 2. Distinguish between spatial domain and frequency domain enhancement techniques.

The spatial domain refers to the image plane itself, and approaches in this category are based on direct manipulation of pixels in an image. Frequency domain processing techniques are based on modifying the Fourier transform of an image.

The term spatial domain refers to the aggregate of pixels composing an image and spatial domain methods are procedures that operate directly on these pixels. Image processing function in the spatial domain may be expressed as.

$$g(x, y) = T[f(x, y)]$$

Where

$f(x, y)$  is the input image

$g(x, y)$  is the processed image and

$T$  is the operator on  $f$  defined over some neighborhood values of

$(x, y)$ .

Frequency domain techniques are based on convolution theorem. Let  $g(x, y)$  be the image formed by the convolution of an image  $f(x, y)$  and linear position invariant operation  $h(x, y)$  i.e.,

$$g(x, y) = h(x, y) * f(x, y)$$

Applying convolution theorem

$$G(u, v) = H(u, v) F(u, v)$$

Where  $G$ ,  $H$  and  $F$  are the Fourier transforms of  $g$ ,  $h$  and  $f$  respectively. In the terminology of linear system the transform  $H(u, v)$  is called the transfer function of the process. The edges in  $f(x, y)$  can be boosted by using  $H(u, v)$  to emphasize the high frequency components of  $F(u, v)$ .

### 3. Explain about Ideal Low Pass Filter (ILPF) in frequency domain.

#### Lowpass Filter:

The edges and other sharp transitions (such as noise) in the gray levels of an image contribute significantly to the high-frequency content of its Fourier transform. Hence blurring (smoothing) is achieved in the frequency domain by attenuating the transform of a given image.

$$G(u, v) = H(u, v) F(u, v)$$

where  $F(u, v)$  is the Fourier transform of an image to be smoothed. The problem is to select a filter transfer function  $H(u, v)$  that yields  $G(u, v)$  by attenuating the high-frequency components of  $F(u, v)$ . The inverse transform then will yield the desired smoothed image  $g(x, y)$ .

#### Ideal Filter:

A 2-D ideal lowpass filter (ILPF) is one whose transfer function satisfies the relation

$$H(u, v) = \begin{cases} 1 & \text{if } D(u, v) \leq D_0 \\ 0 & \text{if } D(u, v) > D_0 \end{cases}$$

where  $D$  is a specified nonnegative quantity, and  $D(u, v)$  is the distance from point  $(u, v)$  to the origin of the frequency plane; that is,

$$D(u, v) = (u^2 + v^2)^{1/2}.$$

Figure 3 (a) shows a 3-D perspective plot of  $H(u, v)$  as a function of  $u$  and  $v$ . The name ideal filter indicates that only frequencies inside a circle of radius

**Fig.3 (a) Perspective plot of an ideal lowpass filter transfer function; (b) filter cross section.**

Do are passed with no attenuation, whereas all frequencies outside this circle are completely attenuated.

The lowpass filters are radially symmetric about the origin. For this type of filter, specifying a cross section extending as a function of distance from the origin along a radial line is sufficient, as Fig. 3 (b) shows. The complete filter transfer function can then be generated by rotating the cross section 360 about the origin. Specification of radially symmetric filters centered on the  $N \times N$  frequency square is based on the assumption that the origin of the Fourier transform has been centered on the square.

For an ideal lowpass filter cross section, the point of transition between  $H(u, v) = 1$  and  $H(u, v) = 0$  is often called the cutoff frequency. In the case of Fig.3 (b), for example, the cutoff frequency is  $D_0$ . As the cross section is rotated about the origin, the point  $D_0$  traces a circle giving a locus of cutoff frequencies, all of which are a distance  $D_0$  from the origin. The cutoff frequency concept is quite useful in specifying filter characteristics. It also serves as a common base for comparing the behavior of different types of filters.

The sharp cutoff frequencies of an ideal lowpass filter cannot be realized with electronic components, although they can certainly be simulated in a computer.

#### 4. Discuss about Butterworth lowpass filter with a suitable example.

##### Butterworth filter:

The transfer function of the Butterworth lowpass (BLPF) of order  $n$  and with cutoff frequency locus at a distance  $D_0$ , from the origin is defined by the relation

$$H(u, v) = \frac{1}{1 + [D(u, v)/D_0]^{2n}}$$

A perspective plot and cross section of the BLPF function are shown in figure 4.

**Fig.4 (a) A Butterworth lowpass filter (b) radial cross section for  $n = 1$ .**

Unlike the ILPF, the BLPF transfer function does not have a sharp discontinuity that establishes a clear cutoff between passed and filtered frequencies. For filters with smooth transfer functions, defining a cutoff frequency locus at points for which  $H(u, v)$  is down to a certain fraction of its maximum value is customary. In the case of above Eq.  $H(u, v) = 0.5$  (down 50 percent from its maximum value of 1) when  $D(u, v) = D_0$ . Another value commonly used is  $1/\sqrt{2}$  of the maximum value of  $H(u, v)$ . The following simple modification yields the desired value when  $D(u, v) = D_0$ :

$$H(u, v) = \frac{1}{1 + [\sqrt{2} - 1][D(u, v)/D_0]^{2n}}$$

$$= \frac{1}{1 + 0.414[D(u, v)/D_0]^{2n}}$$

## 5. Discuss about Ideal High Pass Filter and Butterworth High Pass filter.

### High pass Filtering:

An image can be blurred by attenuating the high-frequency components of its Fourier transform. Because edges and other abrupt changes in gray levels are associated with high-frequency components, image sharpening can be achieved in the frequency domain by a high pass filtering process, which attenuates the low-frequency components without disturbing high-frequency information in the Fourier transform.

### Ideal filter:

2-D ideal high pass filter (IHPF) is one whose transfer function satisfies the relation

$$H(u, v) = \begin{cases} 0 & \text{if } D(u, v) \leq D_0 \\ 1 & \text{if } D(u, v) > D_0 \end{cases}$$

where  $D_0$  is the cutoff distance measured from the origin of the frequency plane. Figure 5.1 shows a perspective plot and cross section of the IHPF function. This filter is the opposite of the ideal lowpass filter, because it completely attenuates all frequencies inside a circle of radius  $D_0$  while passing, without attenuation, all frequencies outside the circle. As in the case of the ideal lowpass filter, the IHPF is not physically realizable.

Fig.5.1 Perspective plot and radial cross section of ideal high pass filter

**Butterworth filter:**

The transfer function of the Butterworth high pass filter (BHPF) of order  $n$  and with cutoff frequency locus at a distance  $D_0$  from the origin is defined by the relation

$$H(u, v) = \frac{1}{1 + [D_0/D(u, v)]^{2n}}$$

Figure 5.2 shows a perspective plot and cross section of the BHPF function. Note that when  $D(u, v) = D_0$ ,  $H(u, v)$  is down to  $1/2$  of its maximum value. As in the case of the Butterworth lowpass filter, common practice is to select the cutoff frequency locus at points for which  $H(u, v)$  is down to  $1/\sqrt{2}$  of its maximum value.

$$\begin{aligned} H(u, v) &= \frac{1}{1 + [\sqrt{2} - 1][D_0/D(u, v)]^{2n}} \\ &= \frac{1}{1 + 0.414[D_0/D(u, v)]^{2n}} \end{aligned}$$

**Fig.5.2 Perspective plot and radial cross section for Butterworth High Pass Filter with  $n = 1$**

## 6. Discuss about Gaussian High Pass and Gaussian Low Pass Filter.

### Gaussian Lowpass Filters:

The form of these filters in two dimensions is given by

$$H(u, v) = e^{-D^2(u, v)/2\sigma^2}$$

where,  $D(u, v)$  is the distance from the origin of the Fourier transform.

**Fig.6.1 (a) Perspective plot of a GLPF transfer function, (b) Filter displayed as an image, (c) Filter radial cross sections for various values of  $D_0$ .**

$\sigma$  is a measure of the spread of the Gaussian curve. By letting  $\sigma = D_0$ , we can express the filter in a more familiar form in terms of the notation:

$$H(u, v) = e^{-D^2(u, v)/2D_0^2}$$

where  $D_0$  is the cutoff frequency. When  $D(u, v) = D_0$ , the filter is down to 0.607 of its maximum value.

### Gaussian Highpass Filters:

The transfer function of the Gaussian highpass filter (GHPF) with cutoff frequency locus at a distance  $D_0$  from the origin is given by

$$H(u, v) = 1 - e^{-D^2(u, v)/2D_0^2}$$

The figure 6.2 shows a perspective plot, image, and cross section of the GHPF function.

**Fig.6.2. Perspective plot, image representation, and cross section of a typical Gaussian high pass filter**

Even the filtering of the smaller objects and thin bars is cleaner with the Gaussian filter.

## 7. Explain how Laplacian is implemented in frequency domain.

### The Laplacian in the Frequency Domain:

It can be shown that

$$\mathfrak{F}\left[\frac{d^n f(x)}{dx^n}\right] = (ju)^n F(u).$$

From this simple expression, it follows that

$$\begin{aligned} \mathfrak{F}\left[\frac{\partial^2 f(x, y)}{\partial x^2} + \frac{\partial^2 f(x, y)}{\partial y^2}\right] &= (ju)^2 F(u, v) + (jv)^2 F(u, v) \\ &= -(u^2 + v^2)F(u, v). \end{aligned}$$

The expression inside the brackets on the left side of the above Eq. is recognized as the Laplacian of  $f(x, y)$ . Thus, we have the important result

$$\mathfrak{F}[\nabla^2 f(x, y)] = -(u^2 + v^2)F(u, v),$$

which simply says that the Laplacian can be implemented in the frequency domain by using the filter

$$H(u, v) = -(u^2 + v^2).$$

As in all filtering operations, the assumption is that the origin of  $F(u, v)$  has been centered by performing the operation  $f(x, y) (-1)^{x+y}$  prior to taking the transform of the image. If  $f$  (and  $F$ ) are of size  $M \times N$ , this operation shifts the center transform so that  $(u, v) = (0, 0)$  is at point  $(M/2, N/2)$  in the frequency rectangle. As before, the center of the filter function also needs to be shifted:

$$H(u, v) = -[(u - M/2)^2 + (v - N/2)^2].$$

The Laplacian-filtered image in the spatial domain is obtained by computing the inverse Fourier transform of  $H(u, v) F(u, v)$ :

$$\nabla^2 f(x, y) = \mathfrak{F}^{-1}\{ -[(u - M/2)^2 + (v - N/2)^2] F(u, v) \}.$$

Conversely, computing the Laplacian in the spatial domain and computing the Fourier transform of the result is equivalent to multiplying  $F(u, v)$  by  $H(u, v)$ . We express this dual relationship in the familiar Fourier-transform-pair notation

$$\nabla^2 f(x, y) \Leftrightarrow -[(u - M/2)^2 + (v - N/2)^2] F(u, v).$$

The spatial domain Laplacian filter function obtained by taking the inverse Fourier transform of Eq. has some interesting properties, as Fig.7 shows. Figure 7(a) is a 3-D perspective plot. The function is centered at  $(M/2, N/2)$ , and its value at the top of the dome is zero. All other values are negative. Figure 7(b) shows  $H(u, v)$  as an image, also centered. Figure 7(c) is the Laplacian in the spatial domain, obtained by multiplying by  $H(u, v)$  by  $(-1)^{u+v}$ , taking the inverse Fourier transform, and multiplying the real part of the result by  $(-1)^{x+y}$ . Figure 7(d) is a zoomed section at about the origin of Fig.7(c). Figure 7(e) is a horizontal gray-level profile passing through the center of the zoomed section. Finally, Fig.7 (f) shows the mask to implement the definition of the discrete Laplacian in the spatial domain.

**Fig.7 (a) 3-D plot of Laplacian in the frequency domain, (b) Image representation of (a), (c) Laplacian in the spatial domain obtained from the inverse DFT of (b) (d) Zoomed section of the origin of (c). (e) Gray-level profile through the center of (d). (f) Laplacian mask**

A horizontal profile through the center of this mask has the same basic shape as the profile in Fig. 7(e) (that is, a negative value between two smaller positive values). We form an enhanced image  $g(x, y)$  by subtracting the Laplacian from the original image:

$$g(x, y) = f(x, y) - \nabla^2 f(x, y).$$

## 8. Write about high boost and high frequency filtering.

### High-Boost Filtering and High-Frequency Emphasis Filtering:

All the filtered images have one thing in common: Their average background intensity has been reduced to near black. This is due to the fact that the highpass filters we applied to those images eliminate the zero-frequency component of their Fourier transforms. In fact, enhancement using the Laplacian does precisely this, by adding back the entire image to the filtered result. Sometimes it is advantageous to increase the contribution made by the original image to the overall filtered result. This approach, called high-boost filtering, is a generalization of unsharp masking. Unsharp masking consists simply of generating a sharp image by subtracting from an image a blurred version of itself. Using frequency domain terminology, this means obtaining a highpass-filtered image by subtracting from the image a lowpass-filtered version of itself. That is

$$f_{hp}(x, y) = f(x, y) - f_{lp}(x, y).$$

High-boost filtering generalizes this by multiplying  $f(x, y)$  by a constant  $A > 1$ :

$$f_{hb} = Af(x, y) - f_{lp}(x, y).$$

Thus, high-boost filtering gives us the flexibility to increase the contribution made by the image to the overall enhanced result. This equation may be written as

$$f_{hb}(x, y) = (A - 1)f(x, y) + f(x, y) - f_{lp}(x, y).$$

Then, using above Eq. we obtain

$$f_{hb}(x, y) = (A - 1)f(x, y) + f_{hp}(x, y).$$

This result is based on a highpass rather than a lowpass image. When  $A = 1$ , high-boost filtering reduces to regular highpass filtering. As  $A$  increases past 1, the contribution made by the image itself becomes more dominant.

We have  $F_{hp}(u, v) = F(u, v) - F_{lp}(u, v)$ . But  $F_{lp}(u, v) = H_{lp}(u, v)F(u, v)$ , where  $H_{lp}$  is the transfer function of a lowpass filter. Therefore, unsharp masking can be implemented directly in the frequency domain by using the composite filter

$$H_{hp}(u, v) = 1 - H_{lp}(u, v).$$

Similarly, high-boost filtering can be implemented with the composite filter

$$H_{hb}(u, v) = (A - 1) + H_{hp}(u, v)$$

with  $A > 1$ . The process consists of multiplying this filter by the (centered) transform of the input image and then taking the inverse transform of the product. Multiplication of the real part of this result by  $(-1)^{x+y}$  gives us the high-boost filtered image  $f_{hb}(x, y)$  in the spatial domain.

## 9. Explain the concept of homomorphic filtering.

### Homomorphic filtering:

The illumination-reflectance model can be used to develop a frequency domain procedure for improving the appearance of an image by simultaneous gray-level range compression and contrast enhancement. An image  $f(x, y)$  can be expressed as the product of illumination and reflectance components:

$$f(x, y) = i(x, y)r(x, y).$$

Equation above cannot be used directly to operate separately on the frequency components of illumination and reflectance because the Fourier transform of the product of two functions is not separable; in other words,

$$\mathfrak{F}\{f(x, y)\} \neq \mathfrak{F}\{i(x, y)\}\mathfrak{F}\{r(x, y)\}.$$

Suppose, however, that we define

$$\begin{aligned} z(x, y) &= \ln f(x, y) \\ &= \ln i(x, y) + \ln r(x, y). \end{aligned}$$

Then

$$\begin{aligned} \mathfrak{F}\{z(x, y)\} &= \mathfrak{F}\{\ln f(x, y)\} \\ &= \mathfrak{F}\{\ln i(x, y)\} + \mathfrak{F}\{\ln r(x, y)\} \end{aligned}$$

or

$$Z(u, v) = F_i(u, v) + F_r(u, v)$$

where  $F_i(u, v)$  and  $F_r(u, v)$  are the Fourier transforms of  $\ln i(x, y)$  and  $\ln r(x, y)$ , respectively. If we process  $Z(u, v)$  by means of a filter function  $H(u, v)$  then, from

$$\begin{aligned} S(u, v) &= H(u, v)Z(u, v) \\ &= H(u, v)F_i(u, v) + H(u, v)F_r(u, v) \end{aligned}$$

where  $S(u, v)$  is the Fourier transform of the result. In the spatial domain,

$$\begin{aligned} s(x, y) &= \mathfrak{F}^{-1}\{S(u, v)\} \\ &= \mathfrak{F}^{-1}\{H(u, v)F_i(u, v)\} + \mathfrak{F}^{-1}\{H(u, v)F_r(u, v)\}. \end{aligned}$$

By letting

$$i'(x, y) = \mathfrak{F}^{-1}\{H(u, v)F_i(u, v)\}$$

and

$$r'(x, y) = \mathfrak{F}^{-1}\{H(u, v)F_r(u, v)\},$$

Now we have

$$s(x, y) = i'(x, y) + r'(x, y).$$

Finally, as  $z(x, y)$  was formed by taking the logarithm of the original image  $f(x, y)$ , the inverse (exponential) operation yields the desired enhanced image, denoted by  $g(x, y)$ ; that is,

$$\begin{aligned} g(x, y) &= e^{s(x, y)} \\ &= e^{i'(x, y)} \cdot e^{r'(x, y)} \\ &= i_0(x, y)r_0(x, y) \end{aligned}$$

where

$$i_0(x, y) = e^{i'(x, y)}$$

Fig.9.1 Homomorphic filtering approach for image enhancement

and

$$r_0(x, y) = e^{r'(x, y)}$$

are the illumination and reflectance components of the output image. The enhancement approach using the foregoing concepts is summarized in Fig. 9.1. This method is based on a special case of a class of systems known as homomorphic systems. In this particular application, the key to the approach is the separation of the illumination and reflectance components achieved. The homomorphic filter function  $H(u, v)$  can then operate on these components separately.

The illumination component of an image generally is characterized by slow spatial variations, while the reflectance component tends to vary abruptly, particularly at the junctions of dissimilar objects. These characteristics lead to associating the low frequencies of the Fourier transform of the logarithm of an image with illumination and the high frequencies with reflectance. Although these associations are rough approximations, they can be used to advantage in image enhancement.

A good deal of control can be gained over the illumination and reflectance components with a homomorphic filter. This control requires specification of a filter function  $H(u, v)$  that affects the low- and high-frequency components of the Fourier transform in different ways. Figure 9.2 shows a cross section of such a filter. If the parameters  $\gamma_L$  and  $\gamma_H$  are chosen so that  $\gamma_L < 1$  and  $\gamma_H > 1$ , the filter function shown in Fig. 9.2 tends to decrease the contribution made by the low frequencies (illumination) and amplify the contribution made by high frequencies (reflectance). The net result is simultaneous dynamic range compression and contrast enhancement.

**Fig.9.2 Cross section of a circularly symmetric filter function  $D(u, v)$  is the distance from the origin of the centered transform.**

**1. Explain about gray level interpolation.**

The distortion correction equations yield non integer values for  $x'$  and  $y'$ . Because the distorted image  $g$  is digital, its pixel values are defined only at integer coordinates. Thus using non integer values for  $x'$  and  $y'$  causes a mapping into locations of  $g$  for which no gray levels are defined. Inferring what the gray-level values at those locations should be, based only on the pixel values at integer coordinate locations, then becomes necessary. The technique used to accomplish this is called gray-level interpolation.

The simplest scheme for gray-level interpolation is based on a nearest neighbor approach. This method, also called zero-order interpolation, is illustrated in Fig. 6.1. This figure shows

(A) The mapping of integer  $(x, y)$  coordinates into fractional coordinates  $(x', y')$  by means of following equations

$$x' = c_1x + c_2y + c_3xy + c_4$$

and

$$y' = c_5x + c_6y + c_7xy + c_8$$

(B) The selection of the closest integer coordinate neighbor to  $(x', y')$ ;

and

(C) The assignment of the gray level of this nearest neighbor to the pixel located at  $(x, y)$ .

Fig. 6.1 Gray-level interpolation based on the nearest neighbor concept.

Although nearest neighbor interpolation is simple to implement, this method often has the drawback of producing undesirable artifacts, such as distortion of straight edges in images of high resolution. Smoother results can be obtained by using more sophisticated techniques, such as cubic convolution interpolation, which fits a surface of the  $\sin(z)/z$  type through a much larger number of neighbors (say, 16) in order to obtain a smooth estimate of the gray level at any desired point. Typical areas in which smoother approximations generally are required include 3-D graphics and medical imaging. The price paid for smoother approximations is additional computational burden. For general-purpose image processing a bilinear interpolation approach that uses the gray levels of the four nearest neighbors usually is adequate. This approach is straightforward. Because the gray level of each of the four integral nearest neighbors of a non integral pair of coordinates  $(x', y')$  is known, the gray-level value at these coordinates, denoted  $v(x', y')$ , can be interpolated from the values of its neighbors by using the relationship

$$v(x', y') = ax' + by' + c x' y' + d$$

where the four coefficients are easily determined from the four equations in four unknowns that can be written using the four known neighbors of  $(x', y')$ . When these coefficients have been determined,  $v(x', y')$  is computed and this value is assigned to the location in  $f\{x, y\}$  that yielded the spatial mapping into location  $(x', y')$ . It is easy to visualize this procedure with the aid of Fig. 6.1. The exception is that, instead of using the gray-level value of the nearest neighbor to  $(x', y')$ , we actually interpolate a value at location  $(x', y')$  and use this value for the gray-level assignment at  $(x, y)$ .

**2. Explain about Wiener filter used for image restoration.**

The inverse filtering approach makes no explicit provision for handling noise. This approach incorporates both the degradation function and statistical characteristics of noise into the restoration process. The method is founded on considering images and noise as random processes, and the objective is to find an estimate  $f$  of the uncorrupted image  $f$  such that the mean square error between them is minimized. This error measure is given by

$$e^2 = E \{ (f - \hat{f})^2 \}$$

where  $E\{\bullet\}$  is the expected value of the argument. It is assumed that the noise and the image are uncorrelated; that one or the other has zero mean; and that the gray levels in the estimate are a linear function of the levels in the degraded image. Based on these conditions, the minimum of the error function is given in the frequency domain by the expression

$$\begin{aligned} \hat{F}(u, v) &= \left[ \frac{H^*(u, v)S_f(u, v)}{S_f(u, v)|H(u, v)|^2 + S_\eta(u, v)} \right] G(u, v) \\ &= \left[ \frac{H^*(u, v)}{|H(u, v)|^2 + S_\eta(u, v)/S_f(u, v)} \right] G(u, v) \\ &= \left[ \frac{1}{H(u, v)} \frac{|H(u, v)|^2}{|H(u, v)|^2 + S_\eta(u, v)/S_f(u, v)} \right] G(u, v) \end{aligned}$$

where we used the fact that the product of a complex quantity with its conjugate is equal to the magnitude of the complex quantity squared. This result is known as the Wiener filter, after N. Wiener [1942], who first proposed the concept in the year shown. The filter, which consists of the terms inside the brackets, also is commonly referred to as the minimum mean square error filter or the least square error filter. The Wiener filter does not have the same problem as the inverse filter with zeros in the degradation function, unless both  $H(u, v)$  and  $S_\eta(u, v)$  are zero for the same value(s) of  $u$  and  $v$ .

The terms in above equation are as follows:

$H(u, v)$  = degradation function

$H^*(u, v)$  = complex conjugate of  $H(u, v)$

$$|H(u, v)|^2 = H^*(u, v) * H(u, v)$$

$S_{\eta}(u, v) = |N(u, v)|^2 =$  power spectrum of the noise

$S_f(u, v) = |F(u, v)|^2 =$  power spectrum of the undegraded image.

As before,  $H(u, v)$  is the transform of the degradation function and  $G(u, v)$  is the transform of the degraded image. The restored image in the spatial domain is given by the inverse Fourier transform of the frequency-domain estimate  $F(u, v)$ . Note that if the noise is zero, then the noise power spectrum vanishes and the Wiener filter reduces to the inverse filter.

When we are dealing with spectrally white noise, the spectrum  $|N(u, v)|^2$  is a constant, which simplifies things considerably. However, the power spectrum of the undegraded image seldom is known. An approach used frequently when these quantities are not known or cannot be estimated is to approximate the equation as

$$\hat{F}(u, v) = \left[ \frac{1}{H(u, v)} \frac{|H(u, v)|^2}{|H(u, v)|^2 + K} \right] G(u, v)$$

where  $K$  is a specified constant.

**3. Explain a Model of the Image Degradation/Restoration Process.**

The Fig. 6.3 shows, the degradation process is modeled as a degradation function that, together with an additive noise term, operates on an input image  $f(x, y)$  to produce a degraded image  $g(x, y)$ . Given  $g(x, y)$ , some knowledge about the degradation function  $H$ , and some knowledge about the additive noise term  $\eta(x, y)$ , the objective of restoration is to obtain an estimate  $\hat{f}(x, y)$  of the original image. the estimate should be as close as possible to the original input image and, in general, the more we know about  $H$  and  $\eta$ , the closer  $\hat{f}(x, y)$  will be to  $f(x, y)$ .

The degraded image is given in the spatial domain by

$$g(x, y) = h(x, y) * f(x, y) + \eta(x, y)$$

where  $h(x, y)$  is the spatial representation of the degradation function and, the symbol  $*$  indicates convolution. Convolution in the spatial domain is equal to multiplication in the frequency domain, hence

$$G(u, v) = H(u, v) F(u, v) + N(u, v)$$

where the terms in capital letters are the Fourier transforms of the corresponding terms in above equation.

Fig. 6.3 model of the image degradation/restoration process.

**4. Explain about the restoration filters used when the image degradation is due to noise only.**

If the degradation present in an image is only due to noise, then,

$$g(x, y) = f(x, y) + \eta(x, y)$$

$$G(u, v) = F(u, v) + N(u, v)$$

The restoration filters used in this case are,

1. Mean filters
2. Order static filters and
3. Adaptive filters

Also read 5, 6, 7 answers.

**5. Explain Mean filters.**

There are four types of mean filters. They are

**(i) Arithmetic mean filter**

This is the simplest of the mean filters. Let  $S_{xy}$  represent the set of coordinates in a rectangular subimage window of size  $m \times n$ , centered at point  $(x, y)$ . The arithmetic mean filtering process computes the average value of the corrupted image  $g(x, y)$  in the area defined by  $S_{xy}$ . The value of the restored image  $f$  at any point  $(x, y)$  is simply the arithmetic mean computed using the pixels in the region defined by  $S_{xy}$ . In other words

$$\hat{f}(x, y) = \frac{1}{mn} \sum_{(s,t) \in S_{xy}} g(s, t).$$

This operation can be implemented using a convolution mask in which all coefficients have value 1/mn

**(ii) Geometric mean filter**

An image restored using a geometric mean filter is given by the expression

$$\hat{f}(x, y) = \left[ \prod_{(s,t) \in S_{xy}} g(s, t) \right]^{\frac{1}{mn}}.$$

Here, each restored pixel is given by the product of the pixels in the subimage window, raised to the power 1/mn. A geometric mean filter achieves smoothing comparable to the arithmetic mean filter, but it tends to lose less image detail in the process.

**(iii) Harmonic mean filter**

The harmonic mean filtering operation is given by the expression

$$\hat{f}(x, y) = \frac{mn}{\sum_{(s,t) \in S_{xy}} \frac{1}{g(s, t)}}.$$

The harmonic mean filter works well for salt noise, but fails for pepper noise. It does well also with other types of noise like Gaussian noise.

**(iv) Contra harmonic mean filter**

The contra harmonic mean filtering operation yields a restored image based on the expression

$$\hat{f}(x, y) = \frac{\sum_{(s,t) \in S_{xy}} g(s, t)^{Q+1}}{\sum_{(s,t) \in S_{xy}} g(s, t)^Q}$$

where Q is called the order of the filter. This filter is well suited for reducing or virtually

eliminating the effects of salt-and-pepper noise. For positive values of  $Q$ , the filter eliminates pepper noise. For negative values of  $Q$  it eliminates salt noise. It cannot do both simultaneously. Note that the contra harmonic filter reduces to the arithmetic mean filter if  $Q = 0$ , and to the harmonic mean filter if  $Q = -1$ .

### 6. Explain the Order-Statistic Filters.

There are four types of Order-Statistic filters. They are

#### (i) Median filter

The best-known order-statistics filter is the median filter, which, as its name implies, replaces the value of a pixel by the median of the gray levels in the neighborhood of that pixel:

$$\hat{f}(x, y) = \text{median}_{(s,t) \in S_{xy}} \{g(s, t)\}.$$

The original value of the pixel is included in the computation of the median. Median filters are quite popular because, for certain types of random noise, they provide excellent noise-reduction capabilities, with considerably less blurring than linear smoothing filters of similar size. Median filters are particularly effective in the presence of both bipolar and unipolar impulse noise.

#### (ii) Max and min filters

Although the median filter is by far the order-statistics filter most used in image processing, it is by no means the only one. The median represents the 50th percentile of a ranked set of numbers, but the reader will recall from basic statistics that ranking lends itself to many other possibilities. For example, using the 100<sup>th</sup> percentile results in the so-called max filter, given by

$$\hat{f}(x, y) = \max_{(s,t) \in S_{xy}} \{g(s, t)\}.$$

This filter is useful for finding the brightest points in an image. Also, because pepper noise has very low values, it is reduced by this filter as a result of the max selection process in the subimage area  $S_{xy}$ .

The 0<sup>th</sup> percentile filter is the min filter.

$$\hat{f}(x, y) = \min_{(s,t) \in S_{xy}} \{g(s, t)\}.$$

This filter is useful for finding the darkest points in an image. Also, it reduces salt noise as a result of the min operation.

### (iii) Midpoint filter

The midpoint filter simply computes the midpoint between the maximum and minimum values in the area encompassed by the filter:

$$\hat{f}(x, y) = \frac{1}{2} \left[ \max_{(s,t) \in S_{xy}} \{g(s, t)\} + \min_{(s,t) \in S_{xy}} \{g(s, t)\} \right].$$

Note that this filter combines order statistics and averaging. This filter works best for randomly distributed noise, like Gaussian or uniform noise.

### (iv) Alpha - trimmed mean filter

It is a filter formed by deleting the  $d/2$  lowest and the  $d/2$  highest gray-level values of  $g(s, t)$  in the neighborhood  $S_{xy}$ . Let  $g_r(s, t)$  represent the remaining  $mn - d$  pixels. A filter formed by averaging these remaining pixels is called an alpha-trimmed mean filter:

$$\hat{f}(x, y) = \frac{1}{mn - d} \sum_{(s,t) \in S_{xy}} g_r(s, t)$$

where the value of  $d$  can range from 0 to  $mn - 1$ . When  $d = 0$ , the alpha- trimmed filter reduces to the arithmetic mean filter. If  $d = (mn - 1)/2$ , the filter becomes a median filter. For other values of  $d$ , the alpha-trimmed filter is useful in situations involving multiple types of noise, such as a combination of salt-and-pepper and Gaussian noise.

**7. Explain the Adaptive Filters.**

Adaptive filters are filters whose behavior changes based on statistical characteristics of the image inside the filter region defined by the  $m \times n$  rectangular window  $S_{xy}$ .

**Adaptive, local noise reduction filter:**

The simplest statistical measures of a random variable are its mean and variance. These are reasonable parameters on which to base an adaptive filter because they are quantities closely related to the appearance of an image. The mean gives a measure of average gray level in the region over which the mean is computed, and the variance gives a measure of average contrast in that region.

This filter is to operate on a local region,  $S_{xy}$ . The response of the filter at any point  $(x, y)$  on which the region is centered is to be based on four quantities: (a)  $g(x, y)$ , the value of the noisy image at  $(x, y)$ ; (b)  $\sigma_n^2$ , the variance of the noise corrupting  $f(x, y)$  to form  $g(x, y)$ ; (c)  $m_L$ , the local mean of the pixels in  $S_{xy}$ ; and (d)  $\sigma_L^2$ , the local variance of the pixels in  $S_{xy}$ .

The behavior of the filter to be as follows:

1. If  $\sigma_n^2$  is zero, the filter should return simply the value of  $g(x, y)$ . This is the trivial, zero-noise case in which  $g(x, y)$  is equal to  $f(x, y)$ .
2. If the local variance is high relative to  $\sigma_n^2$  the filter should return a value close to  $g(x, y)$ . A high local variance typically is associated with edges, and these should be preserved.
3. If the two variances are equal, we want the filter to return the arithmetic mean value of the pixels in  $S_{xy}$ . This condition occurs when the local area has the same properties as the overall image, and local noise is to be reduced simply by averaging.

Adaptive local noise filter is given by,

$$\hat{f}(x, y) = g(x, y) - \frac{\sigma_n^2}{\sigma_L^2} [g(x, y) - m_L].$$

The only quantity that needs to be known or estimated is the variance of the overall noise,  $\sigma_n^2$ . The other parameters are computed from the pixels in  $S_{xy}$  at each location  $(x, y)$  on which the filter window is centered.

**Adaptive median filter:**

The median filter performs well as long as the spatial density of the impulse noise is not large (as a rule of thumb,  $P_a$  and  $P_b$  less than 0.2). The adaptive median filtering can handle impulse noise with probabilities even larger than these. An additional benefit of the adaptive median filter is that it seeks to preserve detail while smoothing nonimpulse noise, something that the "traditional" median filter does not do. The adaptive median filter also works in a rectangular window area  $S_{xy}$ . Unlike those filters, however, the adaptive median filter changes (increases) the size of  $S_{xy}$  during filter operation, depending on certain conditions. The output of the filter is a single value used to replace the value of the pixel at  $(x, y)$ , the particular point on which the window  $S_{xy}$  is centered at a given time.

Consider the following notation:

$z_{min}$  = minimum gray level value in  $S_{xy}$

$z_{max}$  = maximum gray level value in  $S_{xy}$

$z_{med}$  = median of gray levels in  $S_{xy}$

$z_{xy}$  = gray level at coordinates  $(x, y)$

$S_{max}$  = maximum allowed size of  $S_{xy}$ .

The adaptive median filtering algorithm works in two levels, denoted level A and level B, as follows:

**Level A:**       $A1 = z_{med} - z_{min}$

$A2 = z_{med} - z_{max}$

If  $A1 > 0$  AND  $A2 < 0$ , Go to level B

Else increase the window size

If window size  $\leq S_{max}$  repeat level A

Else output  $z_{xy}$

**Level B:**       $B1 = z_{xy} - z_{min}$

$B2 = z_{xy} - z_{max}$

If  $B1 > 0$  AND  $B2 < 0$ , output  $z_{xy}$

Else output  $z_{med}$

**8. Explain a simple Image Formation Model.**

An image is represented by two-dimensional functions of the form  $f(x, y)$ . The value or amplitude of  $f$  at spatial coordinates  $(x, y)$  is a positive scalar quantity whose physical meaning is determined by the source of the image. When an image is generated from a physical process, its values are proportional to energy radiated by a physical source (e.g., electromagnetic waves). As a consequence,  $f(x, y)$  must be nonzero and finite; that is,

$$0 < f(x, y) < \infty \quad \dots (1)$$

The function  $f(x, y)$  may be characterized by two components:

A) The amount of source illumination incident on the scene being viewed.

B) The amount of illumination reflected by the objects in the scene.

Appropriately, these are called the illumination and reflectance components and are denoted by  $i(x, y)$  and  $r(x, y)$ , respectively. The two functions combine as a product to form  $f(x, y)$ .

$$f(x, y) = i(x, y) r(x, y) \quad \dots (2)$$

where

$$0 < i(x, y) < \infty \quad \dots (3)$$

and

$$0 < r(x, y) < 1 \quad \dots (4)$$

Equation (4) indicates that reflectance is bounded by 0 (total absorption) and 1 (total reflectance). The nature of  $i(x, y)$  is determined by the illumination source, and  $r(x, y)$  is determined by the characteristics of the imaged objects. It is noted that these expressions also are applicable to images formed via transmission of the illumination through a medium, such as a chest X-ray.

### 9. Write brief notes on inverse filtering.

The simplest approach to restoration is direct inverse filtering, where  $F(u, v)$ , the transform of the original image is computed simply by dividing the transform of the degraded image,  $G(u, v)$ , by the degradation function

$$\hat{F}(u, v) = \frac{G(u, v)}{H(u, v)}.$$

The divisions are between individual elements of the functions.

It tells that even if the degradation function is known the undegraded image cannot be recovered [the inverse Fourier transform of  $F(u, v)$ ] exactly because  $N(u, v)$  is a random function whose Fourier transform is not known.

If the degradation has zero or very small values, then the ratio  $N(u, v)/H(u, v)$  could easily dominate the estimate  $F(u, v)$ .

One approach to get around the zero or small-value problem is to limit the filter frequencies to values near the origin.  $H(0, 0)$  is equal to the average value of  $h(x, y)$  and that this

is usually the highest value of  $H(u, v)$  in the frequency domain. Thus, by limiting the analysis to frequencies near the origin, the probability of encountering zero values is reduced.

### 10. Write about Noise Probability Density Functions.

The following are among the most common PDFs found in image processing applications.

#### Gaussian noise

Because of its mathematical tractability in both the spatial and frequency domains, Gaussian (also called normal) noise models are used frequently in practice. In fact, this tractability is so convenient that it often results in Gaussian models being used in situations in which they are marginally applicable at best.

The PDF of a Gaussian random variable,  $z$ , is given by

$$p(z) = \frac{1}{\sqrt{2\pi}\sigma} e^{-(z-\mu)^2/2\sigma^2} \dots (1)$$

where z represents gray level, μ is the mean of average value of z, and a σ is its standard deviation. The standard deviation squared, σ<sup>2</sup>, is called the variance of z. A plot of this function is shown in Fig. 5.10. When z is described by Eq. (1), approximately 70% of its values will be in the range [(μ - σ), (μ + σ)], and about 95% will be in the range [(μ - 2σ), (μ + 2σ)].

**Rayleigh noise**

The PDF of Rayleigh noise is given by

$$p(z) = \begin{cases} \frac{2}{b} (z - a)e^{-(z-a)^2/b} & \text{for } z \geq a \\ 0 & \text{for } z < a. \end{cases}$$

The mean and variance of this density are given by

$$\mu = a + \sqrt{\pi b}/4$$

$$\sigma^2 = b(4 - \pi)/4$$

Figure 5.10 shows a plot of the Rayleigh density. Note the displacement from the origin and the fact that the basic shape of this density is skewed to the right. The Rayleigh density can be quite useful for approximating skewed histograms.

**Erlang (Gamma) noise**

The PDF of Erlang noise is given by

$$p(z) = \begin{cases} \frac{a^b z^{b-1}}{(b - 1)!} e^{-az} & \text{for } z \geq 0 \\ 0 & \text{for } z < 0 \end{cases}$$

where the parameters are such that a > 0, b is a positive integer, and "!" indicates factorial. The mean and variance of this density are given by

$$\mu = b / a$$

$$\sigma^2 = b / a^2$$

### Exponential noise

The PDF of exponential noise is given by

$$p(z) = \begin{cases} ae^{-az} & \text{for } z \geq 0 \\ 0 & \text{for } z < 0 \end{cases}$$

The mean of this density function is given by

$$\mu = 1 / a$$

$$\sigma^2 = 1 / a^2$$

This PDF is a special case of the Erlang PDF, with  $b = 1$ .

### Uniform noise

The PDF of uniform noise is given by

$$p(z) = \begin{cases} \frac{1}{b - a} & \text{if } a \leq z \leq b \\ 0 & \text{otherwise.} \end{cases}$$

The mean of this density function is given by

$$\mu = a + b / 2$$

$$\sigma^2 = (b - a)^2 / 12$$

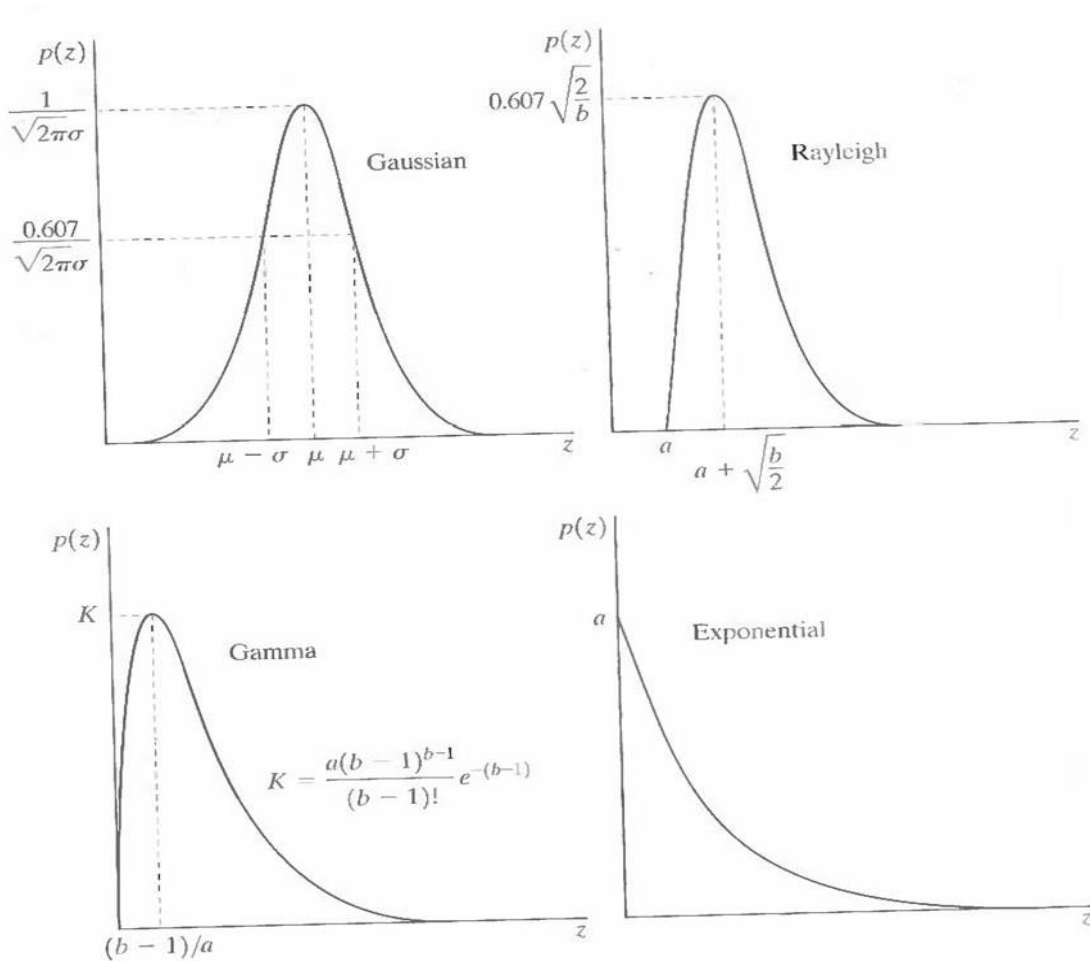

### Impulse (salt-and-pepper) noise

The PDF of (bipolar) impulse noise is given by

$$p(z) = \begin{cases} P_a & \text{for } z = a \\ P_b & \text{for } z = b \\ 0 & \text{otherwise} \end{cases}$$

If  $b > a$ , gray-level  $b$  will appear as a light dot in the image. Conversely, level  $a$  will appear like a dark dot. If either  $P_a$  or  $P_b$  is zero, the impulse noise is called unipolar. If neither probability is zero, and especially if they are approximately equal, impulse noise values will resemble salt-and-pepper granules randomly distributed over the image. For this reason, bipolar impulse noise also is called salt-and-pepper noise. Shot and spike noise also are terms used to refer to this type of noise.

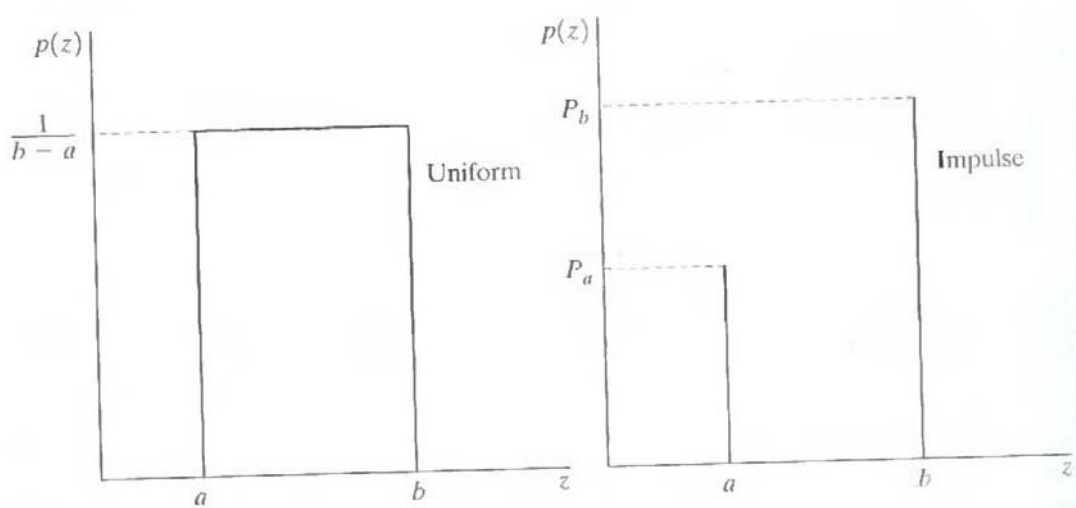

Fig.5.10 Some important probability density functions

### 11. Enumerate the differences between the image enhancement and image restoration.

(i) Image enhancement techniques are heuristic procedures designed to manipulate an image in order to take advantage of the psychophysical aspects of the human system. Whereas image restoration techniques are basically reconstruction techniques by which a degraded image is reconstructed by using some of the prior knowledge of the degradation phenomenon.

(ii) Image enhancement can be implemented by spatial and frequency domain technique, whereas image restoration can be implemented by frequency domain and algebraic techniques.

(iii) The computational complexity for image enhancement is relatively less when compared to the computational complexity for image restoration, since algebraic methods require manipulation of a large number of simultaneous equations. But, under some conditions, computational complexity can be reduced to the same level as that required by traditional frequency domain techniques.

(iv) Image enhancement techniques are problem oriented, whereas image restoration techniques are general and are oriented towards modeling the degradation and applying the reverse process in order to reconstruct the original image.

(v) Masks are used in spatial domain methods for image enhancement, whereas masks are not used for image restoration techniques.

(vi) Contrast stretching is considered as an image enhancement technique because it is based on the pleasing aspects of the review, whereas removal of image blur by applying a deblurring function is considered as an image restoration technique.

**12. Explain about iterative nonlinear restoration using the Lucy–Richardson algorithm.**

Lucy-Richardson algorithm is a nonlinear restoration method used to recover a latent image which is blurred by a Point Spread Function (psf). It is also known as Richardson-Lucy deconvolution.

With as the point spread function, the pixels in observed image are expressed as,

$$C_i = \sum_j P_{ij} u_j$$

Here,

- $u_j$  = Pixel value at location  $j$  in the image
- $C_i$  = Observed value at  $i^{\text{th}}$  pixel location

The L-R algorithm cannot be used in application in which the psf ( $P_{ij}$ ) is dependent on one or more unknown variables.

The L-R algorithm is based on maximum-likelihood formulation, in this formulation Poisson statistics are used to model the image. If the likelihood of model is increased, then the result is an equation which satisfies when the following iteration converges.

$$\hat{f}_{k+1}(x, y) = \hat{f}_k(x, y) \left[ h(-x, -y) \times \frac{g(x, y)}{h(x, y) \times \hat{f}_k(x, y)} \right]$$

Here,

$f$  = Estimation of undegraded image.

The factor  $f$  which is present in the right side denominator leads to non-linearity. Since, the algorithm is a type of nonlinear restorations; hence it is stopped when satisfactory result is obtained.

The basic syntax of function deconvlucy with the L-R algorithm is implemented is given below.

**fr** = Deconvlucy (g, psf, NUMIT, DAMPAR, WEIGHT)

Here the parameters are,

$g$  = Degraded image

$f_r$  = Restored image

psf = Point spread function

NUMIT = Total number of iterations.

The remaining two parameters are,

### **DAMPAR**

The DAMPAR parameter is a scalar parameter which is used to determine the deviation of resultant image with the degraded image ( $g$ ). The pixels which get deviated from their original value within the DAMPAR, for these pixels iterations are cancelled so as to reduce noise generation and present essential image information.

### **WEIGHT**

WEIGHT parameter gives a weight to each and every pixel. It is array of size similar to that of degraded image ( $g$ ). In applications where a pixel leads to improper image is removed by assigning it to a weight as 0'. The pixels may also be given weights depending upon the flat-field correction, which is essential according to image array. Weights are used in applications such as blurring with specified psf. They are used to remove the pixels which are present at the boundary of the image and are blurred separately by psf.

If the array size of psf is  $n \times n$  then the width of weight of border of zeroes being used is  $\text{ceil}(n / 2)$

1. Explain about color fundamentals.

Color of an object is determined by the nature of the light reflected from it. When a beam of sunlight passes through a glass prism, the emerging beam of light is not white but consists instead of a continuous spectrum of colors ranging from violet at one end to red at the other. As Fig. 5.1.1 shows, the color spectrum may be divided into six broad regions: violet, blue, green, yellow, orange, and red. When viewed in full color (Fig. 5.1.2), no color in the spectrum ends abruptly, but rather each color blends smoothly into the next.

Fig. 5.1.1 Color spectrum seen by passing white light through a prism.

Fig. 5.1.2 Wavelengths comprising the visible range of the electromagnetic spectrum.

As illustrated in Fig. 5.1.2, visible light is composed of a relatively narrow band of frequencies in the electromagnetic spectrum. A body that reflects light that is balanced in all visible wavelengths appears white to the observer. However, a body that favors reflectance in a limited range of the visible spectrum exhibits some shades of color. For example, green objects reflect light with wavelengths primarily in the 500 to 570 nm range while absorbing most of the energy at other wavelengths.

Characterization of light is central to the science of color. If the light is achromatic (void of color), its only attribute is its intensity, or amount. Achromatic light is what viewers see on a black and white television set.

Three basic quantities are used to describe the quality of a chromatic light source: radiance, luminance, and brightness.

**Radiance:**

Radiance is the total amount of energy that flows from the light source, and it is usually measured in watts (W).

**Luminance:**

Luminance, measured in lumens (lm), gives a measure of the amount of energy an observer perceives from a light source. For example, light emitted from a source operating in the far infrared region of the spectrum could have significant energy (radiance), but an observer would hardly perceive it; its luminance would be almost zero.

**Brightness:**

Brightness is a subjective descriptor that is practically impossible to measure. It embodies the achromatic notion of intensity and is one of the key factors in describing color sensation.

Fig. 5.1.3 Absorption of light by the red, green, and blue cones in the human eye as a function of wavelength.

Cones are the sensors in the eye responsible for color vision. Detailed experimental evidence has established that the 6 to 7 million cones in the human eye can be divided into three principal sensing categories, corresponding roughly to red, green, and blue. Approximately 65% of all cones are sensitive to red light, 33% are sensitive to green light, and only about 2% are sensitive to blue (but the blue cones are the most sensitive). Figure 5.1.3 shows average experimental curves detailing the absorption of light by the red, green, and blue cones in the eye. Due to these absorption characteristics of the human eye, colors are seen as variable combinations of the so-called primary colors red (R), green (G), and blue (B).

The primary colors can be added to produce the secondary colors of light --magenta (red plus blue), cyan (green plus blue), and yellow (red plus green). Mixing the three primaries, or a secondary with its opposite primary color, in the right intensities produces white light.

The characteristics generally used to distinguish one color from another are brightness, hue, and saturation. Brightness embodies the chromatic notion of intensity. Hue is an attribute associated with the dominant wavelength in a mixture of light waves. Hue represents dominant color as perceived by an observer. Saturation refers to the relative purity or the amount of white light mixed with a hue. The pure spectrum colors are fully saturated. Colors such as pink (red and white) and lavender (violet and white) are less saturated, with the degree of saturation being inversely proportional to the amount of white light-added.

Hue and saturation taken together are called chromaticity, and, therefore, a color may be characterized by its brightness and chromaticity.

## **2. Explain RGB color model.**

The purpose of a color model (also called color space or color system) is to facilitate the specification of colors in some standard, generally accepted way. In essence, a color model is a specification of a coordinate system and a subspace within that system where each color is represented by a single point.

### **The RGB Color Model:**

In the RGB model, each color appears in its primary spectral components of red, green, and blue. This model is based on a Cartesian coordinate system. The color subspace of interest is the cube shown in Fig. 5.2, in which RGB values are at three corners; cyan, magenta, and yellow are at three other corners; black is at the origin; and white is at the corner farthest from the origin. In this model, the gray scale (points of equal RGB values) extends from black to white along the line joining these two points. The different colors in this model are points on or inside

the cube, and are defined by vectors extending from the origin. For convenience, the assumption is that all color values have been normalized so that the cube shown in Fig. 5.2 is the unit cube. That is, all values of R, G, and B are assumed to be in the range [0, 1].

Fig. 5.2 Schematic of the RGB color cube.

Images represented in the RGB color model consist of three component images, one for each primary color. When fed into an RGB monitor, these three images combine on the phosphor screen to produce a composite color image. The number of bits used to represent each pixel in RGB space is called the pixel depth.

Consider an RGB image in which each of the red, green, and blue images is an 8-bit image. Under these conditions each RGB color pixel [that is, a triplet of values (R, G, B)] is said to have a depth of 24 bits (3 image planes times the number of bits per plane). The term full-color image is used often to denote a 24-bit RGB color image. The total number of colors in a 24-bit RGB image is  $(2^8)^3 = 16,777,216$ .

RGB is ideal for image color generation (as in image capture by a color camera or image display in a monitor screen), but its use for color description is much more limited.

### 3. Explain CMY color model.

Cyan, magenta, and yellow are the secondary colors of light or, alternatively, the primary colors of pigments. For example, when a surface coated with cyan pigment is illuminated with white light, no red light is reflected from the surface. That is, cyan subtracts red light from reflected white light, which itself is composed of equal amounts of red, green, and blue light.

Most devices that deposit colored pigments on paper, such as color printers and copiers, require CMY data input or perform an RGB to CMY conversion internally. This conversion is performed using the simple operation (1) where, again, the assumption is that all color values have been normalized to the range [0, 1]. Equation (1) demonstrates that light reflected from a surface coated with pure cyan does not contain red (that is,  $C = 1 - R$  in the equation).

$$\begin{bmatrix} C \\ M \\ Y \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} - \begin{bmatrix} R \\ G \\ B \end{bmatrix} \quad (1)$$

Similarly, pure magenta does not reflect green, and pure yellow does not reflect blue. Equation (1) also reveals that RGB values can be obtained easily from a set of CMY values by subtracting the individual CMY values from 1. As indicated earlier, in image processing this color model is used in connection with generating hardcopy output, so the inverse operation from CMY to RGB generally is of little practical interest.

Equal amounts of the pigment primaries, cyan, magenta, and yellow should produce black. In practice, combining these colors for printing produces a muddy-looking black.

#### 4. Explain HSI color model.

When humans view a color object, we describe it by its hue, saturation, and brightness. Hue is a color attribute that describes a pure color (pure yellow, orange, or red), whereas saturation gives a measure of the degree to which a pure color is diluted by white light. Brightness is a subjective descriptor that is practically impossible to measure. It embodies the achromatic notion of intensity and is one of the key factors in describing color sensation.

Intensity (gray level) is a most useful descriptor of monochromatic images. This quantity definitely is measurable and easily interpretable. The HSI (hue, saturation, intensity) color model, decouples the intensity component from the color-carrying information (hue and saturation) in a color image. As a result, the HSI model is an ideal tool for developing image processing algorithms based on color descriptions that are natural and intuitive to humans.

In Fig 5.4 the primary colors are separated by  $120^\circ$ . The secondary colors are  $60^\circ$  from the primaries, which means that the angle between secondaries is also  $120^\circ$ . Figure 5.4(b) shows the same hexagonal shape and an arbitrary color point (shown as a dot). The hue of the point is determined by an angle from some reference point. Usually (but not always) an angle of  $0^\circ$  from the red axis designates 0 hue, and the hue increases counterclockwise from there. The saturation (distance from the vertical axis) is the length of the vector from the origin to the point. Note that the origin is defined by the intersection of the color plane with the vertical intensity axis.

The important components of the HSI color space are the vertical intensity axis, the length of the vector to a color point, and the angle this vector makes with the red axis.

Fig 5.4 Hue and saturation in the HSI color model.

**6. Discuss procedure for conversion from RGB color model to HSI color model.**

Given an image in RGB color format, the H component of each RGB pixel is obtained using the equation

$$H = \begin{cases} \theta & \text{if } B \leq G \\ 360 - \theta & \text{if } B > G \end{cases} \quad (1)$$

With

$$\theta = \cos^{-1} \left\{ \frac{\frac{1}{2}[(R - G) + (R - B)]}{[(R - G)^2 + (R - B)(G - B)]^{1/2}} \right\}$$

The saturation component is given by

$$S = 1 - \frac{3}{(R + G + B)} [\min(R, G, B)].$$

Finally, the intensity component is given by

It is assumed that the RGB values have been normalized to the range [0, 1] and that angle  $\theta$  is measured with respect to the red axis of the HST space. Hue can be normalized to the range [0, 1] by dividing by  $360^\circ$  all values resulting from Eq. (1). The other two HSI components already are in this range if the given RGB values are in the interval [0, 1].

### 7. Discuss procedure for conversion from HSI color model to RGB color model.

Given values of HSI in the interval [0,1 ], one can find the corresponding RGB values in the same range. The applicable equations depend on the values of H. There are three sectors of interest, corresponding to the  $120^\circ$  intervals in the separation of primaries.

#### RG sector ( $0^\circ \leq H < 120^\circ$ ):

When H is in this sector, the RGB components are given by the equations

$$B = I (1 - S)$$

$$G = 3 I - (R + B)$$

$$R = I [1 + (S * \cos H / \cos(60^\circ - H))]$$

#### GB sector ( $120^\circ \leq H < 240^\circ$ ):

If the given value of H is in this sector, first subtract  $120^\circ$  from it.

$$H = H - 120^\circ$$

Then the RGB components are

$$R = I (1 - S)$$

$$B = 3 I - (R + G)$$

$$G = I [1 + (S * \cos H / \cos(60^\circ - H))]$$

#### BR sector ( $240^\circ \leq H \leq 360^\circ$ ):

If H is in this range, subtract  $240^\circ$  from it

$$H = H - 240^\circ$$

Then the RGB components are

$$G = I (1 - S)$$

$$R = 3 I - (B + G)$$

$$B = I [1 + (S * \cos H / \cos(60^\circ - H))]$$

### 8. Explain about pseudocolor image processing.

Pseudocolor (also called false color) image processing consists of assigning colors to gray values based on a specified criterion. The term pseudo or false color is used to differentiate the process of assigning colors to monochrome images from the processes associated with true color images. The process of gray level to color transformations is known as pseudocolor image processing.

The two techniques used for pseudocolor image processing are,

- (i) Intensity Slicing
- (ii) Gray Level to Color Transformation

#### (i) Intensity Slicing:

The technique of intensity (sometimes called density) slicing and color coding is one of the simplest examples of pseudocolor image processing. If an image is interpreted as a 3-D function (intensity versus spatial coordinates), the method can be viewed as one of placing planes parallel to the coordinate plane of the image; each plane then "slices" the function in the area of intersection. Figure 5.8 shows an example of using a plane at  $f(x, y) = l_i$  to slice the image function into two levels.

If a different color is assigned to each side of the plane shown in Fig. 5.8, any pixel whose gray level is above the plane will be coded with one color, and any pixel below the plane will be coded with the other. Levels that lie on the plane itself may be arbitrarily assigned one of the two colors. The result is a two-color image whose relative appearance can be controlled by moving the slicing plane up and down the gray-level axis.

In general, the technique may be summarized as follows. Let  $[0, L - 1]$  represent the gray scale, let level  $l_0$  represent black  $[f(x, y) = 0]$ , and level  $l_{L - 1}$  represent white  $[f(x, y) = L - 1]$ . Suppose that  $P$  planes perpendicular to the intensity axis are defined at levels  $l_1, l_2, \dots, l_p$ . Then, assuming that  $0 < P < L - 1$ , the  $P$  planes partition the gray scale into  $P + 1$  intervals,  $V_1, V_2, \dots, V_{P + 1}$ . Gray-level to color assignments are made according to the relation

$$f(x, y) = C_k \quad \text{if } f(x, y) \in V_k$$

where  $c_k$  is the color associated with the  $k$ th intensity interval  $V_k$  defined by the partitioning planes at  $l = k - 1$  and  $l = k$ .

Fig 5.8.1 Geometric interpretation of the intensity-slicing technique.

The idea of planes is useful primarily for a geometric interpretation of the intensity-slicing technique. Figure 5.8.2 shows an alternative representation that defines the same mapping as in Fig. 5.8.1. According to the mapping function shown in Fig. 5.8.2, any input gray level is assigned one of two colors, depending on whether it is above or below the value of  $l_i$ . When more levels are used, the mapping function takes on a staircase form.

Fig 5.8.2 An alternative representation of the intensity-slicing technique.

**(ii) Gray Level to Color Transformation:**

The idea underlying this approach is to perform three independent transformations on the gray level of any input pixel. The three results are then fed separately into the red, green, and blue channels of a color television monitor. This method produces a composite image whose color content is modulated by the nature of the transformation functions. Note that these are transformations on the gray-level values of an image and are not functions of position.

In intensity slicing, piecewise linear functions of the gray levels are used to generate colors. On the other hand, this method can be based on smooth, nonlinear functions, which, as might be expected, gives the technique considerable flexibility.

Fig. 5.8.3 Functional block diagram for pseudocolor image processing.

The output of each transformation is a composite image.

**9. Write about the basics of full color image processing.**

Full-color image processing approaches fall into two major categories. In the first category, each component image is processed individually and then form a composite processed color image from the individually processed components. In the second category, one works with color pixels directly. Because full-color images have at least three components, color pixels really are vectors. For example, in the RGB system, each color point can be interpreted as a vector extending from the origin to that point in the RGB coordinate system.

Let  $c$  represent an arbitrary vector in RGB color space:

$$\mathbf{c} = \begin{bmatrix} c_R \\ c_G \\ c_B \end{bmatrix} = \begin{bmatrix} R \\ G \\ B \end{bmatrix}. \tag{1}$$

This equation indicates that the components of  $\mathbf{c}$  are simply the RGB components of a color image at a point. If the color components are a function of coordinates  $(x, y)$  by using the notation

$$\mathbf{c}(x, y) = \begin{bmatrix} c_R(x, y) \\ c_G(x, y) \\ c_B(x, y) \end{bmatrix} = \begin{bmatrix} R(x, y) \\ G(x, y) \\ B(x, y) \end{bmatrix}. \tag{2}$$

For an image of size  $M \times N$ , there are  $MN$  such vectors,  $\mathbf{c}(x, y)$ , for  $x = 0, 1, 2, \dots, M-1$ ;  $y = 0, 1, 2, \dots, N-1$ .

It is important to keep clearly in mind that Eq. (2) depicts a vector whose components are spatial variables in  $x$  and  $y$ .

In order for per-color-component and vector-based processing to be equivalent, two conditions have to be satisfied: First, the process has to be applicable to both vectors and scalars. Second, the operation on each component of a vector must be independent of the other components.

Fig 9 Spatial masks for gray-scale and RGB color images.

Fig 9 shows neighborhood spatial processing of gray-scale and full-color images.

Suppose that the process is neighborhood averaging. In Fig. 9(a), averaging would be accomplished by summing the gray levels of all the pixels in the neighborhood and dividing by the total number of pixels in the neighborhood. In Fig. 9(b), averaging would be done by summing all the vectors in the neighborhood and dividing each component by the total number of vectors in the neighborhood. But each component of the average vector is the sum of the pixels in the image corresponding to that component, which is the same as the result that would be obtained if the averaging were done on a per-color-component basis and then the vector was formed.

### 10. Explain about color segmentation process.

Segmentation is a process that partitions an image into regions and partitioning an image into regions based on color is known as color segmentation.

#### Segmentation in HSI Color Space:

If anybody want to segment an image based on color, and in addition, to carry out the process on individual planes, it is natural to think first of the HSI space because color is conveniently represented in the hue image. Typically, saturation is used as a masking image in order to isolate further regions of interest in the hue image. The intensity image is used less frequently for segmentation of color images because it carries no color information.

#### Segmentation in RGB Vector Space:

Although, working in HSI space is more intuitive, segmentation is one area in which better results generally are obtained by using RGB color vectors. The approach is straightforward. Suppose that the objective is to segment objects of a specified color range in an RGB image. Given a set of sample color points representative of the colors of interest, we obtain an estimate of the "average" color that we wish to segment. Let this average color be denoted by the RGB vector  $\mathbf{a}$ . The objective of segmentation is to classify each RGB pixel in a given image as having a color in the specified range or not. In order to perform this comparison, it is necessary to have a measure of similarity. One of the simplest measures is the Euclidean distance. Let  $\mathbf{z}$  denote an arbitrary point in RGB space.  $\mathbf{z}$  is similar to  $\mathbf{a}$  if the distance between them is less than a specified threshold,  $D_0$ . The Euclidean distance between  $\mathbf{z}$  and  $\mathbf{a}$  is given by

$$\begin{aligned} D(\mathbf{z}, \mathbf{a}) &= \|\mathbf{z} - \mathbf{a}\| \\ &= [(\mathbf{z} - \mathbf{a})^T(\mathbf{z} - \mathbf{a})]^{1/2} \\ &= [(z_R - a_R)^2 + (z_G - a_G)^2 + (z_B - a_B)^2]^{1/2} \end{aligned}$$

where the subscripts R, G, and B, denote the RGB components of vectors  $\mathbf{a}$  and  $\mathbf{z}$ . The locus of points such that  $D(\mathbf{z}, \mathbf{a}) \leq D_0$  is a solid sphere of radius  $D_0$ .

Points contained within or on the surface of the sphere satisfy the specified color criterion; points outside the sphere do not. Coding these two sets of points in the image with, say, black and white, produces a binary segmented image.

A useful generalization of previous equation is a distance measure of the form

$$D(\mathbf{z}, \mathbf{a}) = [(\mathbf{z}-\mathbf{a})^T \mathbf{C}^{-1} (\mathbf{z}-\mathbf{a})]^{1/2}$$

where  $\mathbf{C}$  is the covariance matrix<sup>1</sup> of the samples representative of the color to be segmented.

The above equation represents an ellipse with color points such that  $D(\mathbf{z}, \mathbf{a}) \leq D_0$ .

## 1. What are the derivative operators useful in image segmentation? Explain their role in segmentation.

### Gradient operators:

First-order derivatives of a digital image are based on various approximations of the 2-D gradient. The gradient of an image  $f(x, y)$  at location  $(x, y)$  is defined as the vector

$$\nabla f = \begin{bmatrix} G_x \\ G_y \end{bmatrix} = \begin{bmatrix} \frac{\partial f}{\partial x} \\ \frac{\partial f}{\partial y} \end{bmatrix}.$$

It is well known from vector analysis that the gradient vector points in the direction of maximum rate of change of  $f$  at coordinates  $(x, y)$ . An important quantity in edge detection is the magnitude of this vector, denoted by  $Af$ , where

$$\nabla f = \text{mag}(\nabla f) = [G_x^2 + G_y^2]^{1/2}.$$

This quantity gives the maximum rate of increase of  $f(x, y)$  per unit distance in the direction of  $Af$ . It is a common (although not strictly correct) practice to refer to  $Af$  also as the gradient. The direction of the gradient vector also is an important quantity. Let  $\alpha(x, y)$  represent the direction angle of the vector  $Af$  at  $(x, y)$ . Then, from vector analysis,

$$\alpha(x, y) = \tan^{-1}\left(\frac{G_y}{G_x}\right)$$

where the angle is measured with respect to the  $x$ -axis. The direction of an edge at  $(x, y)$  is perpendicular to the direction of the gradient vector at that point. Computation of the gradient of an image is based on obtaining the partial derivatives  $\frac{\partial f}{\partial x}$  and  $\frac{\partial f}{\partial y}$  at every pixel location. Let the  $3 \times 3$  area shown in Fig. 1.1 (a) represent the gray levels in a neighborhood of an image. One of the simplest ways to implement a first-order partial derivative at point  $z_5$  is to use the following Roberts cross-gradient operators:

and

$$G_x = (z_9 - z_5)$$

$$G_y = (z_8 - z_6).$$

These derivatives can be implemented for an entire image by using the masks shown in Fig. 1.1(b). Masks of size 2 X 2 are awkward to implement because they do not have a clear center. An approach using masks of size 3 X 3 is given by

Fig.1.1 A 3 X 3 region of an image (the z's are gray-level values) and various masks used to

**compute the gradient at point labeled  $z_5$ .**

$$G_x = (z_7 + z_8 + z_9) - (z_1 + z_2 + z_3)$$

and

$$G_y = (z_3 + z_6 + z_9) - (z_1 + z_4 + z_7).$$

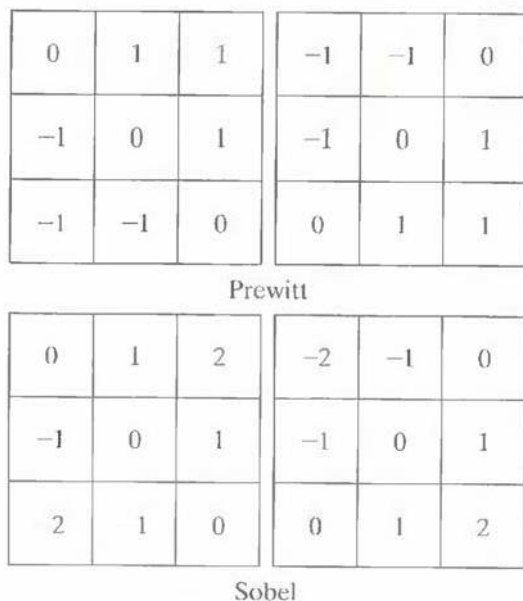

A weight value of 2 is used to achieve some smoothing by giving more importance to the center point. Figures 1.1(f) and (g), called the Sobel operators, and are used to implement these two equations. The Prewitt and Sobel operators are among the most used in practice for computing digital gradients. The Prewitt masks are simpler to implement than the Sobel masks, but the latter have slightly superior noise-suppression characteristics, an important issue when dealing with derivatives. Note that the coefficients in all the masks shown in Fig. 1.1 sum to 0, indicating that they give a response of 0 in areas of constant gray level, as expected of a derivative operator.

The masks just discussed are used to obtain the gradient components  $G_x$  and  $G_y$ . Computation of the gradient requires that these two components be combined. However, this implementation is not always desirable because of the computational burden required by squares and square roots. An approach used frequently is to approximate the gradient by absolute values:

$$\nabla f \approx |G_x| + |G_y|.$$

This equation is much more attractive computationally, and it still preserves relative changes in gray levels. However, this is not an issue when masks such as the Prewitt and Sobel masks are used to compute  $G_x$  and  $G_y$ .

It is possible to modify the 3 X 3 masks in Fig. 1.1 so that they have their strongest responses along the diagonal directions. The two additional Prewitt and Sobel masks for detecting discontinuities in the diagonal directions are shown in Fig. 1.2.

**Fig.1.2 Prewitt and Sobel masks for detecting diagonal edges**

**The Laplacian:**

The Laplacian of a 2-D function f(x, y) is a second-order derivative defined as

$$\nabla^2 f = \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2}.$$

For a 3 X 3 region, one of the two forms encountered most frequently in practice is

$$\nabla^2 f = 4z_5 - (z_2 + z_4 + z_6 + z_8)$$

**Fig.1.3 Laplacian masks used to implement Eqns. above.**

where the  $z$ 's are defined in Fig. 1.1(a). A digital approximation including the diagonal neighbors is given by

$$\nabla^2 f = 8z_5 - (z_1 + z_2 + z_3 + z_4 + z_6 + z_7 + z_8 + z_9).$$

Masks for implementing these two equations are shown in Fig. 1.3. We note from these masks that the implementations of Eqns. are isotropic for rotation increments of  $90^\circ$  and  $45^\circ$ , respectively.

## 2. Write about edge detection.

Intuitively, an edge is a set of connected pixels that lie on the boundary between two regions. Fundamentally, an edge is a "local" concept whereas a region boundary, owing to the way it is defined, is a more global idea. A reasonable definition of "edge" requires the ability to measure gray-level transitions in a meaningful way. We start by modeling an edge intuitively. This will lead us to formalism in which "meaningful" transitions in gray levels can be measured. Intuitively, an ideal edge has the properties of the model shown in Fig. 2.1(a). An ideal edge according to this model is a set of connected pixels (in the vertical direction here), each of which is located at an orthogonal step transition in gray level (as shown by the horizontal profile in the figure).

In practice, optics, sampling, and other image acquisition imperfections yield edges that are blurred, with the degree of blurring being determined by factors such as the quality of the image acquisition system, the sampling rate, and illumination conditions under which the image is acquired. As a result, edges are more closely modeled as having a "ramp like" profile, such as the one shown in Fig.2.1 (b).

**Fig.2.1 (a) Model of an ideal digital edge (b) Model of a ramp edge. The slope of the ramp is proportional to the degree of blurring in the edge.**

The slope of the ramp is inversely proportional to the degree of blurring in the edge. In this model, we no longer have a thin (one pixel thick) path. Instead, an edge point now is any point contained in the ramp, and an edge would then be a set of such points that are connected. The "thickness" of the edge is determined by the length of the ramp, as it transitions from an initial to a final gray level. This length is determined by the slope, which, in turn, is determined by the degree of blurring. This makes sense: Blurred edges tend to be thick and sharp edges tend to be thin. Figure 2.2(a) shows the image from which the close-up in Fig. 2.1(b) was extracted. Figure 2.2(b) shows a horizontal gray-level profile of the edge between the two regions. This figure also shows the first and second derivatives of the gray-level profile. The first derivative is positive at the points of transition into and out of the ramp as we move from left to right along the profile; it is constant for points in the ramp; and is zero in areas of constant gray level. The second derivative is positive at the transition associated with the dark side of the edge, negative at the transition associated with the light side of the edge, and zero along the ramp and in areas of constant gray level. The signs of the derivatives in Fig. 2.2(b) would be reversed for an edge that transitions from light to dark.

We conclude from these observations that the magnitude of the first derivative can be used to detect the presence of an edge at a point in an image (i.e. to determine if a point is on a ramp). Similarly, the sign of the second derivative can be used to determine whether an edge pixel lies

on the dark or light side of an edge. We note two additional properties of the second derivative around an edge: A) It produces two values for every edge in an image (an undesirable feature); and B) an imaginary straight line joining the extreme positive and negative values of the second derivative would cross zero near the midpoint of the edge. This zero-crossing property of the second derivative is quite useful for locating the centers of thick edges.

**Fig.2.2 (a) Two regions separated by a vertical edge (b) Detail near the edge, showing a gray-level profile, and the first and second derivatives of the profile.**

### 3. Explain about the edge linking procedures.

The different methods for edge linking are as follows

- (i) Local processing
- (ii) Global processing via the Hough Transform
- (iii) Global processing via graph-theoretic techniques.

#### (i) Local Processing:

One of the simplest approaches for linking edge points is to analyze the characteristics of pixels in a small neighborhood (say, 3 X 3 or 5 X 5) about every point (x, y) in an image that has been labeled an edge point. All points that are similar according to a set of predefined criteria are linked, forming an edge of pixels that share those criteria.

The two principal properties used for establishing similarity of edge pixels in this kind of analysis are (1) the strength of the response of the gradient operator used to produce the edge pixel; and (2) the direction of the gradient vector. The first property is given by the value of  $A_f$ .

Thus an edge pixel with coordinates  $(x_0, y_0)$  in a predefined neighborhood of  $(x, y)$ , is similar in magnitude to the pixel at  $(x, y)$  if

$$|\nabla f(x, y) - \nabla f(x_0, y_0)| \leq E$$

The direction (angle) of the gradient vector is given by Eq. An edge pixel at  $(x_0, y_0)$  in the predefined neighborhood of  $(x, y)$  has an angle similar to the pixel at  $(x, y)$  if

$$|\alpha(x, y) - \alpha(x_0, y_0)| < A$$

where  $A$  is a nonnegative angle threshold. The direction of the edge at  $(x, y)$  is perpendicular to the direction of the gradient vector at that point.

A point in the predefined neighborhood of  $(x, y)$  is linked to the pixel at  $(x, y)$  if both magnitude and direction criteria are satisfied. This process is repeated at every location in the image. A record must be kept of linked points as the center of the neighborhood is moved from pixel to pixel. A simple bookkeeping procedure is to assign a different gray level to each set of linked edge pixels.

**(ii) Global processing via the Hough Transform:**

In this process, points are linked by determining first if they lie on a curve of specified shape. We now consider global relationships between pixels. Given  $n$  points in an image, suppose that we want to find subsets of these points that lie on straight lines. One possible solution is to first find all lines determined by every pair of points and then find all subsets of points that are close to particular lines. The problem with this procedure is that it involves finding  $n(n - 1)/2 \sim n^2$  lines and then performing  $(n)(n(n - 1))/2 \sim n^3$  comparisons of every point to all lines. This approach is computationally prohibitive in all but the most trivial applications.

Hough [1962] proposed an alternative approach, commonly referred to as the Hough transform. Consider a point  $(x_i, y_i)$  and the general equation of a straight line in slope-intercept form,  $y_i = a.x_i + b$ . Infinitely many lines pass through  $(x_i, y_i)$  but they all satisfy the equation  $y_i = a.x_i + b$  for varying values of  $a$  and  $b$ . However, writing this equation as  $b = -a.x_i + y_i$ , and considering the  $ab$ -plane (also called parameter space) yields the equation of a single line for a fixed pair  $(x_i, y_i)$ . Furthermore, a second point  $(x_j, y_j)$  also has a line in parameter space associated with it, and this line intersects the line associated with  $(x_i, y_i)$  at  $(a', b')$ , where  $a'$  is the slope and  $b'$  the intercept of the line containing both  $(x_i, y_i)$  and  $(x_j, y_j)$  in the  $xy$ -plane. In fact, all points contained on this line have lines in parameter space that intersect at  $(a', b')$ . Figure 3.1 illustrates these concepts.

**Fig.3.1 (a) xy-plane (b) Parameter space**

**Fig.3.2 Subdivision of the parameter plane for use in the Hough transform**

The computational attractiveness of the Hough transform arises from subdividing the parameter space into so-called accumulator cells, as illustrated in Fig. 3.2, where  $(a_{\max}, a_{\min})$  and  $(b_{\max}, b_{\min})$ , are the expected ranges of slope and intercept values. The cell at coordinates  $(i, j)$ , with accumulator value  $A(i, j)$ , corresponds to the square associated with parameter space coordinates  $(a_i, b_j)$ .

Initially, these cells are set to zero. Then, for every point  $(x_k, y_k)$  in the image plane, we let the parameter  $a$  equal each of the allowed subdivision values on the  $a$ -axis and solve for the corresponding  $b$  using the equation  $b = -x_k a + y_k$ . The resulting  $b$ 's are then rounded off to the nearest allowed value in the  $b$ -axis. If a choice of  $a_p$  results in solution  $b_q$ , we let  $A(p, q) = A(p, q) + 1$ . At the end of this procedure, a value of  $Q$  in  $A(i, j)$  corresponds to  $Q$  points in the  $xy$ -plane lying on the line  $y = a_i x + b_j$ . The number of subdivisions in the  $ab$ -plane determines the accuracy of the co linearity of these points. Note that subdividing the  $a$  axis into  $K$  increments gives, for every point  $(x_k, y_k)$ ,  $K$  values of  $b$  corresponding to the  $K$  possible values of  $a$ . With  $n$  image points, this method involves  $nK$  computations. Thus the procedure just discussed is linear in  $n$ , and the product  $nK$  does not approach the number of computations discussed at the beginning unless  $K$  approaches or exceeds  $n$ .

A problem with using the equation  $y = ax + b$  to represent a line is that the slope approaches infinity as the line approaches the vertical. One way around this difficulty is to use the normal representation of a line:

$$x \cos\theta + y \sin\theta = \rho$$

Figure 3.3(a) illustrates the geometrical interpretation of the parameters used. The use of this representation in constructing a table of accumulators is identical to the method discussed for the slope-intercept representation. Instead of straight lines, however, the loci are sinusoidal curves in the  $\rho\theta$ -plane. As before,  $Q$  collinear points lying on a line  $x \cos\theta_j + y \sin\theta_j = \rho$ , yield  $Q$  sinusoidal curves that intersect at  $(p_i, \theta_j)$  in the parameter space. Incrementing  $\theta$  and solving for the corresponding  $p$  gives  $Q$  entries in accumulator  $A(i, j)$  associated with the cell determined by  $(p_i, \theta_j)$ . Figure 3.3 (b) illustrates the subdivision of the parameter space.

**Fig.3.3 (a) Normal representation of a line (b) Subdivision of the  $\rho\theta$ -plane into cells**

The range of angle  $\theta$  is  $\pm 90^\circ$ , measured with respect to the  $x$ -axis. Thus with reference to Fig. 3.3 (a), a horizontal line has  $\theta = 0^\circ$ , with  $\rho$  being equal to the positive  $x$ -intercept. Similarly, a vertical line has  $\theta = 90^\circ$ , with  $p$  being equal to the positive  $y$ -intercept, or  $\theta = -90^\circ$ , with  $\rho$  being equal to the negative  $y$ -intercept.

### (iii) Global processing via graph-theoretic techniques

In this process we have a global approach for edge detection and linking based on representing edge segments in the form of a graph and searching the graph for low-cost paths that correspond to significant edges. This representation provides a rugged approach that performs well in the presence of noise.

**Fig.3.4 Edge element between pixels p and q**

We begin the development with some basic definitions. A graph  $G = (N,U)$  is a finite, nonempty set of nodes  $N$ , together with a set  $U$  of unordered pairs of distinct elements of  $N$ . Each pair  $(n_i, n_j)$  of  $U$  is called an arc. A graph in which the arcs are directed is called a directed graph. If an arc is directed from node  $n_i$  to node  $n_j$ , then  $n_j$  is said to be a successor of the parent node  $n_i$ . The process of identifying the successors of a node is called expansion of the node. In each graph we define levels, such that level 0 consists of a single node, called the start or root node, and the nodes in the last level are called goal nodes. A cost  $c(n_i, n_j)$  can be associated with every arc  $(n_i, n_j)$ . A sequence of nodes  $n_1, n_2, \dots, n_k$ , with each node  $n_i$  being a successor of node  $n_{i-1}$  is called a path from  $n_1$  to  $n_k$ . The cost of the entire path is

$$c = \sum_{i=2}^k c(n_{i-1}, n_i).$$

The following discussion is simplified if we define an edge element as the boundary between two pixels  $p$  and  $q$ , such that  $p$  and  $q$  are 4-neighbors, as Fig.3.4 illustrates. Edge elements are identified by the  $xy$ -coordinates of points  $p$  and  $q$ . In other words, the edge element in Fig. 3.4 is defined by the pairs  $(x_p, y_p)$   $(x_q, y_q)$ . Consistent with the definition an edge is a sequence of connected edge elements.

We can illustrate how the concepts just discussed apply to edge detection using the 3 X 3 image shown in Fig. 3.5 (a). The outer numbers are pixel

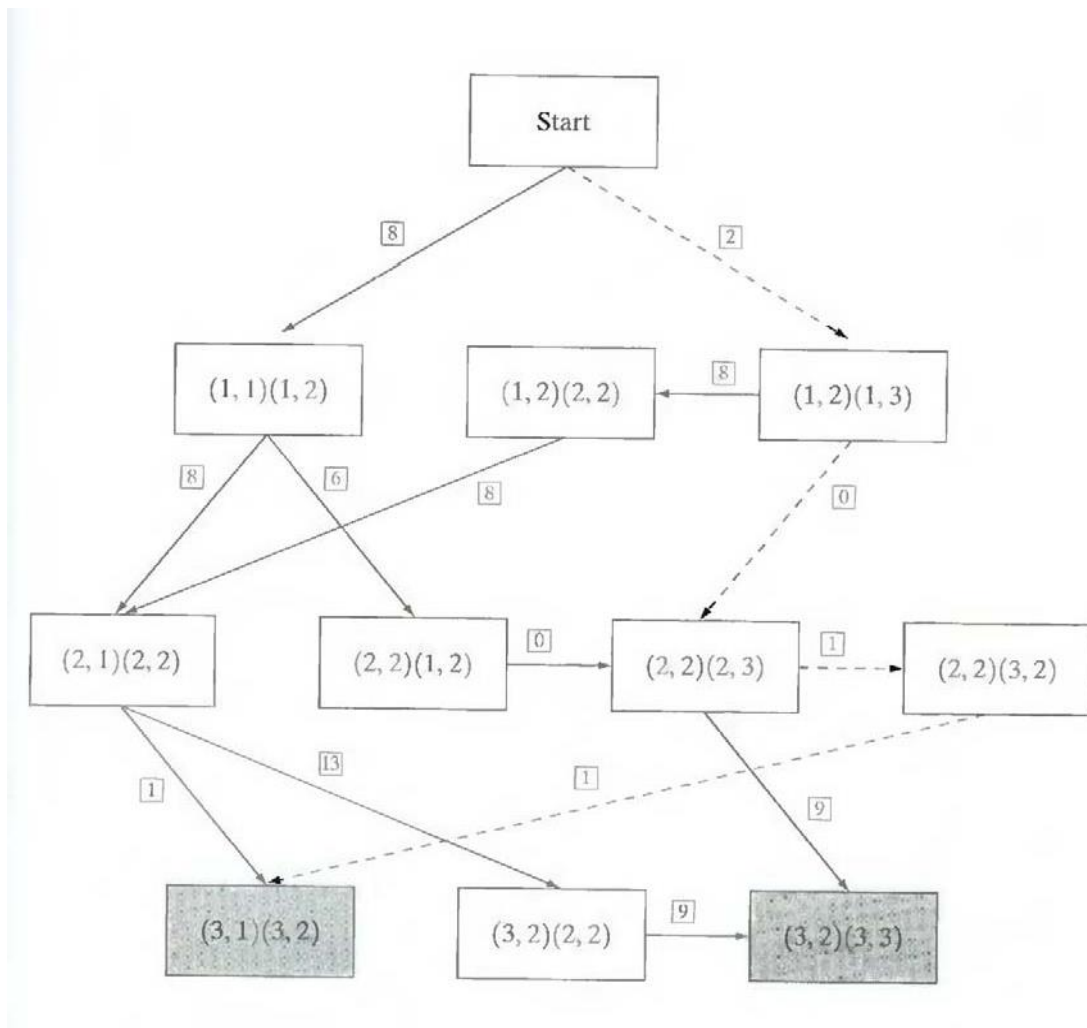

**Fig.3.5 (a) A 3 X 3 image region, (b) Edge segments and their costs, (c) Edge corresponding to the lowest-cost path in the graph shown in Fig. 3.6**

coordinates and the numbers in brackets represent gray-level values. Each edge element, defined by pixels p and q, has an associated cost, defined as

$$c(p, q) = H - [f(p) - f(q)]$$

where H is the highest gray-level value in the image (7 in this case), and f(p) and f(q) are the gray-level values of p and q, respectively. By convention, the point p is on the right-hand side of the direction of travel along edge elements. For example, the edge segment (1, 2) (2, 2) is between points (1, 2) and (2, 2) in Fig. 3.5 (b). If the direction of travel is to the right, then p is the point with coordinates (2, 2) and q is point with coordinates (1, 2); therefore,  $c(p, q) = 7 - [7 - 6] = 6$ . This cost is shown in the box below the edge segment. If, on the other hand, we are traveling to the left between the same two points, then p is point (1, 2) and q is (2, 2). In this case the cost is 8, as shown above the edge segment in Fig. 3.5(b). To simplify the discussion, we assume that edges start in the top row and terminate in the last row, so that the first element of an edge can be only between points (1, 1), (1, 2) or (1, 2), (1, 3). Similarly, the last edge element has to be between points (3, 1), (3, 2) or (3, 2), (3, 3). Keep in mind that p and q are 4-neighbors, as noted earlier. Figure 3.6 shows the graph for this problem. Each node (rectangle) in the graph corresponds to an edge element from Fig. 3.5. An arc exists between two nodes if the two corresponding edge elements taken in succession can be part of an edge.

**Fig. 3.6** Graph for the image in Fig.3.5 (a). The lowest-cost path is shown dashed.

As in Fig. 3.5 (b), the cost of each edge segment, is shown in a box on the side of the arc leading into the corresponding node. Goal nodes are shown shaded. The minimum cost path is shown dashed, and the edge corresponding to this path is shown in Fig. 3.5 (c).

#### 4. What is thresholding? Explain about global thresholding.

##### Thresholding:

Because of its intuitive properties and simplicity of implementation, image thresholding enjoys a central position in applications of image segmentation.

##### Global Thresholding:

The simplest of all thresholding techniques is to partition the image histogram by using a single global threshold,  $T$ . Segmentation is then accomplished by scanning the image pixel by pixel and labeling each pixel as object or back-ground, depending on whether the gray level of that pixel is greater or less than the value of  $T$ . As indicated earlier, the success of this method depends entirely on how well the histogram can be partitioned.

**Fig.4.1** FIGURE 10.28 (a) Original image, (b) Image histogram, (c) Result of global thresholding with  $T$  midway between the maximum and minimum gray levels.

Figure 4.1(a) shows a simple image, and Fig. 4.1(b) shows its histogram. Figure 4.1(c) shows the result of segmenting Fig. 4.1(a) by using a threshold  $T$  midway between the maximum and minimum gray levels. This threshold achieved a "clean" segmentation by eliminating the shadows and leaving only the objects themselves. The objects of interest in this case are darker than the background, so any pixel with a gray level  $\leq T$  was labeled black (0), and any pixel with a gray level  $\geq T$  was labeled white (255). The key objective is merely to generate a binary image, so the black-white relationship could be reversed. The type of global thresholding just described can be expected to be successful in highly controlled environments. One of the areas in which this often is possible is in industrial inspection applications, where control of the illumination usually is feasible.

The threshold in the preceding example was specified by using a heuristic approach, based on visual inspection of the histogram. The following algorithm can be used to obtain  $T$  automatically:

1. Select an initial estimate for  $T$ .
2. Segment the image using  $T$ . This will produce two groups of pixels:  $G_1$  consisting of all pixels with gray level values  $>T$  and  $G_2$  consisting of pixels with values  $< T$ .
3. Compute the average gray level values  $\mu_1$  and  $\mu_2$  for the pixels in regions  $G_1$  and  $G_2$ .
4. Compute a new threshold value:

$$T = \frac{1}{2}(\mu_1 + \mu_2).$$

5. Repeat steps 2 through 4 until the difference in  $T$  in successive iterations is smaller than a predefined parameter  $T_0$ .

When there is reason to believe that the background and object occupy comparable areas in the image, a good initial value for  $T$  is the average gray level of the image. When objects are small compared to the area occupied by the background (or vice versa), then one group of pixels will dominate the histogram and the average gray level is not as good an initial choice. A more appropriate initial value for  $T$  in cases such as this is a value midway between the maximum and minimum gray levels. The parameter  $T_0$  is used to stop the algorithm after changes become small in terms of this parameter. This is used when speed of iteration is an important issue.

## 5. Explain about basic adaptive thresholding process used in image segmentation.

### Basic Adaptive Thresholding:

Imaging factors such as uneven illumination can transform a perfectly segmentable histogram into a histogram that cannot be partitioned effectively by a single global threshold. An approach for handling such a situation is to divide the original image into subimages and then utilize a different threshold to segment each subimage. The key issues in this approach are how to subdivide the image and how to estimate the threshold for each resulting subimage. Since the threshold used for each pixel depends on the location of the pixel in terms of the subimages, this type of thresholding is adaptive.

**Fig.5 (a) Original image, (b) Result of global thresholding. (c) Image subdivided into individual subimages (d) Result of adaptive thresholding.**

We illustrate adaptive thresholding with an example. Figure 5(a) shows the image, which we concluded could not be thresholded effectively with a single global threshold. In fact, Fig. 5(b) shows the result of thresholding the image with a global threshold manually placed in the valley of its histogram. One approach to reduce the effect of nonuniform illumination is to subdivide the image into smaller subimages, such that the illumination of each subimage is approximately uniform. Figure 5(c) shows such a partition, obtained by subdividing the image into four equal parts, and then subdividing each part by four again. All the subimages that did not contain a boundary between object and background had variances of less than 75. All subimages containing boundaries had variances in excess of 100. Each subimage with variance greater than 100 was segmented with a threshold computed for that subimage using the algorithm. The initial value for  $T$  in each case was selected as the point midway between the minimum and maximum gray levels in the subimage. All subimages with variance less than 100 were treated as one composite image, which was segmented using a single threshold estimated using the same algorithm. The result of segmentation using this procedure is shown in Fig. 5(d).

With the exception of two subimages, the improvement over Fig. 5(b) is evident. The boundary between object and background in each of the improperly segmented subimages was small and dark, and the resulting histogram was almost unimodal.

## **6. Explain in detail the threshold selection based on boundary characteristics.**

### **Use of Boundary Characteristics for Histogram Improvement and Local Thresholding:**

It is intuitively evident that the chances of selecting a "good" threshold are enhanced considerably if the histogram peaks are tall, narrow, symmetric, and separated by deep valleys. One approach for improving the shape of histograms is to consider only those pixels that lie on or near the edges between objects and the background. An immediate and obvious improvement is that histograms would be less dependent on the relative sizes of objects and the background. For instance, the histogram of an image composed of a small object on a large background area (or vice versa) would be dominated by a large peak because of the high concentration of one type of pixels.

If only the pixels on or near the edge between object and the background were used, the resulting histogram would have peaks of approximately the same height. In addition, the probability that any of those given pixels lies on an object would be approximately equal to the probability that it lies on the background, thus improving the symmetry of the histogram peaks.

Finally, as indicated in the following paragraph, using pixels that satisfy some simple measures based on gradient and Laplacian operators has a tendency to deepen the valley between histogram

peaks.

The principal problem with the approach just discussed is the implicit assumption that the edges between objects and background are known. This information clearly is not available during segmentation, as finding a division between objects and background is precisely what segmentation is all about. However, an indication of whether a pixel is on an edge may be obtained by computing its gradient. In addition, use of the Laplacian can yield information regarding whether a given pixel lies on the dark or light side of an edge. The average value of the Laplacian is 0 at the transition of an edge, so in practice the valleys of histograms formed from the pixels selected by a gradient/Laplacian criterion can be expected to be sparsely populated. This property produces the highly desirable deep valleys.

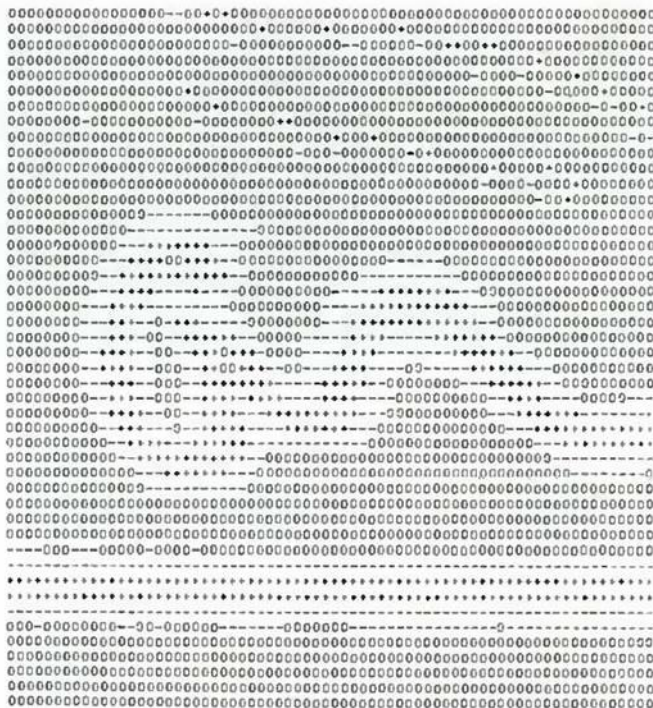

The gradient  $\nabla f$  at any point  $(x, y)$  in an image can be found. Similarly, the Laplacian  $\nabla^2 f$  can also be found. These two quantities may be used to form a three-level image, as follows:

$$s(x, y) = \begin{cases} 0 & \text{if } \nabla f < T \\ + & \text{if } \nabla f \geq T \text{ and } \nabla^2 f \geq 0 \\ - & \text{if } \nabla f \geq T \text{ and } \nabla^2 f < 0 \end{cases}$$

where the symbols 0, +, and - represent any three distinct gray levels, T is a threshold, and the gradient and Laplacian are computed at every point  $(x, y)$ . For a dark object on a light background, the use of the Eqn. produces an image  $s(x, y)$  in which (1) all pixels that are not on an edge (as determined by  $\nabla f$  being less than T) are labeled 0; (2) all pixels on the dark side of an edge are labeled +; and (3) all pixels on the light side of an edge are labeled -. The symbols + and - in Eq. above are reversed for a light object on a dark background. Figure 6.1 shows the labeling produced by Eq. for an image of a dark, underlined stroke written on a light background.

The information obtained with this procedure can be used to generate a segmented, binary image in which 1's correspond to objects of interest and 0's correspond to the background. The transition (along a horizontal or vertical scan line) from a light background to a dark object must be characterized by the occurrence of a - followed by a + in  $s(x, y)$ . The interior of the object is composed of pixels that are labeled either 0 or +. Finally, the transition from the object back to the background is characterized by the occurrence of a + followed by a -. Thus a horizontal or vertical scan line containing a section of an object has the following structure:

$$(\dots)(-, +)(0 \text{ or } +)(+, -)(\dots)$$

**Fig.6.1 Image of a handwritten stroke coded by using Eq. discussed above**

where (...) represents any combination of +, -, and 0. The innermost parentheses contain object points and are labeled 1. All other pixels along the same scan line are labeled 0, with the exception of any other sequence of (- or +) bounded by (-, +) and (+, -).

**Fig.6.2 (a) Original image, (b) Image segmented by local thresholding.**

Figure 6.2 (a) shows an image of an ordinary scenic bank check. Figure 6.3 shows the histogram as a function of gradient values for pixels with gradients greater than 5. Note that this histogram has two dominant modes that are symmetric, nearly of the same height, and are separated by a distinct valley. Finally, Fig. 6.2(b) shows the segmented image obtained by with  $T$  at or near the midpoint of the valley. Note that this example is an illustration of local thresholding, because the value of  $T$  was determined from a histogram of the gradient and Laplacian, which are local properties.

**Fig.6.3 Histogram of pixels with gradients greater than 5**

## 7. Explain about region based segmentation.

### Region-Based Segmentation:

The objective of segmentation is to partition an image into regions. We approached this problem by finding boundaries between regions based on discontinuities in gray levels, whereas segmentation was accomplished via thresholds based on the distribution of pixel properties, such as gray-level values or color.

### Basic Formulation:

Let  $R$  represent the entire image region. We may view segmentation as a process that partitions  $R$  into  $n$  subregions,  $R_1, R_2, \dots, R_n$ , such that

- (a)  $\bigcup_{i=1}^n R_i = R.$   
 (b)  $R_i$  is a connected region,  $i = 1, 2, \dots, n.$   
 (c)  $R_i \cap R_j = \emptyset$  for all  $i$  and  $j, i \neq j.$   
 (d)  $P(R_i) = \text{TRUE}$  for  $i = 1, 2, \dots, n.$   
 (e)  $P(R_i \cup R_j) = \text{FALSE}$  for  $i \neq j.$

Here,  $P(R_i)$  is a logical predicate defined over the points in set  $R_i$  and  $\emptyset$  is the null set. Condition (a) indicates that the segmentation must be complete; that is, every pixel must be in a region. Condition (b) requires that points in a region must be connected in some predefined sense. Condition (c) indicates that the regions must be disjoint. Condition (d) deals with the properties that must be satisfied by the pixels in a segmented region—for example  $P(R_i) = \text{TRUE}$  if all pixels in  $R_i$ , have the same gray level. Finally, condition (e) indicates that regions  $R_i$  and  $R_j$  are different in the sense of predicate  $P$ .

### Region Growing:

As its name implies, region growing is a procedure that groups pixels or subregions into larger regions based on predefined criteria. The basic approach is to start with a set of "seed" points and from these grow regions by appending to each seed those neighboring pixels that have properties similar to the seed (such as specific ranges of gray level or color). When a priori information is not available, the procedure is to compute at every pixel the same set of properties that ultimately will be used to assign pixels to regions during the growing process. If the result of these computations shows clusters of values, the pixels whose properties place them near the centroid of these clusters can be used as seeds.

The selection of similarity criteria depends not only on the problem under consideration, but also on the type of image data available. For example, the analysis of land-use satellite imagery depends heavily on the use of color. This problem would be significantly more difficult, or even impossible, to handle without the inherent information available in color images. When the images are monochrome, region analysis must be carried out with a set of descriptors based on gray levels and spatial properties (such as moments or texture).

Basically, growing a region should stop when no more pixels satisfy the criteria for inclusion in that region. Criteria such as gray level, texture, and color, are local in nature and do not take into account the "history" of region growth. Additional criteria that increase the power of a region-growing algorithm utilize the concept of size, likeness between a candidate pixel and the pixels grown so far (such as a comparison of the gray level of a candidate and the average gray level of

the grown region), and the shape of the region being grown. The use of these types of descriptors is based on the assumption that a model of expected results is at least partially available.

Figure 7.1 (a) shows an X-ray image of a weld (the horizontal dark region) containing several cracks and porosities (the bright, white streaks running horizontally through the middle of the image). We wish to use region growing to segment the regions of the weld failures. These segmented features could be used for inspection, for inclusion in a database of historical studies, for controlling an automated welding system, and for other numerous applications.

**Fig.7.1 (a) Image showing defective welds, (b) Seed points, (c) Result of region growing, (d) Boundaries of segmented ; defective welds (in black).**

The first order of business is to determine the initial seed points. In this application, it is known that pixels of defective welds tend to have the maximum allowable digital value B55 in this case). Based on this information, we selected as starting points all pixels having values of 255. The points thus extracted from the original image are shown in Fig. 10.40(b). Note that many of the points are clustered into seed regions.

The next step is to choose criteria for region growing. In this particular example we chose two criteria for a pixel to be annexed to a region: (1) The absolute gray-level difference between any pixel and the seed had to be less than 65. This number is based on the histogram shown in Fig. 7.2 and represents the difference between 255 and the location of the first major valley to the left, which is representative of the highest gray level value in the dark weld region. (2) To be included in one of the regions, the pixel had to be 8-connected to at least one pixel in that region.

If a pixel was found to be connected to more than one region, the regions were merged. Figure 7.1 (c) shows the regions that resulted by starting with the seeds in Fig. 7.2 (b) and utilizing the criteria defined in the previous paragraph. Superimposing the boundaries of these regions on the original image [Fig. 7.1(d)] reveals that the region-growing procedure did indeed segment the defective welds with an acceptable degree of accuracy. It is of interest to note that it was not necessary to specify any stopping rules in this case because the criteria for region growing were sufficient to isolate the features of interest.

**Fig.7.2 Histogram of Fig. 7.1 (a)**

**Region Splitting and Merging:**

The procedure just discussed grows regions from a set of seed points. An alternative is to subdivide an image initially into a set of arbitrary, disjoint regions and then merge and/or split the regions in an attempt to satisfy the conditions. A split and merge algorithm that iteratively works toward satisfying these constraints is developed.

Let  $R$  represent the entire image region and select a predicate  $P$ . One approach for segmenting  $R$  is to subdivide it successively into smaller and smaller quadrant regions so that, for any region  $R_i$ ,  $P(R_i) = \text{TRUE}$ . We start with the entire region. If  $P(R) = \text{FALSE}$ , we divide the image into quadrants. If  $P$  is  $\text{FALSE}$  for any quadrant, we subdivide that quadrant into subquadrants, and so on. This particular splitting technique has a convenient representation in the form of a so-called quadtree (that is, a tree in which nodes have exactly four descendants), as illustrated in Fig. 7.3. Note that the root of the tree corresponds to the entire image and that each node corresponds to a subdivision. In this case, only  $R_4$  was subdivided further.

**Fig. 7.3 (a) Partitioned image (b) Corresponding quadtree.**

If only splitting were used, the final partition likely would contain adjacent regions with identical properties. This drawback may be remedied by allowing merging, as well as splitting. Satisfying the constraints, requires merging only adjacent regions whose combined pixels satisfy the predicate  $P$ . That is, two adjacent regions  $R_j$  and  $R_k$  are merged only if  $P(R_j \cup R_k) = \text{TRUE}$ .

The preceding discussion may be summarized by the following procedure, in which, at any step we

1. Split into four disjoint quadrants any region  $R_i$ , for which  $P(R_i) = \text{FALSE}$ .
2. Merge any adjacent regions  $R_j$  and  $R_k$  for which  $P(R_j \cup R_k) = \text{TRUE}$ .

3. Stop when no further merging or splitting is possible.

Several variations of the preceding basic theme are possible. For example, one possibility is to split the image initially into a set of blocks. Further splitting is carried out as described previously, but merging is initially limited to groups of four blocks that are descendants in the quadtree representation and that satisfy the predicate  $P$ . When no further mergings of this type are possible, the procedure is terminated by one final merging of regions satisfying step 2. At this point, the merged regions may be of different sizes. The principal advantage of this approach is that it uses the same quadtree for splitting and merging, until the final merging step.
